The CMD is caused by bipartite begomoviruses. Unlike TYLCV, the CMDs have two circular genomes (bipartite) i.e., DNA-A and DNA-B. As recombination is the driving force for geminivirus evolution, therefore CMDs are no exceptions. Indeed, the EACMV-UG strain is a recombinant for the CP region between EACMV and ACMV. The sequence analysis revealed that EACMV-UG strain gained ~400–550 nt from the CP of ACMV through recombination. Over the years, the molecular sequencing revealed nine different species of begomoviruses occurring in single or mixed infection. These species includes, *African cassava mosaic virus* (ACMV), *African cassava mosaic Burkina Faso virus* (ACMBFV), *East African cassava mosaic virus* (EACMV), *East African cassava mosaic Cameroon virus* (EACMCV), *East African cassava mosaic Kenya virus* (EACMKV), *South African cassava mosaic virus* (SACMV), *East African cassava mosaic Malawi virus* (EACMMV), *East African cassava mosaic Zanzibar virus* (EACMZV), and *cassava mosaic Madagascar virus* (CMMGV). The co-infection of different CMDs can lead to synergism and new recombinants are produced with variable virulence can arise.

Epidemiology

The literature suggests that CMGs mainly spread through infected cassava cuttings, however, whitefly (*Bemisia tabaci*) also played an important role in spreading the virus to other field crops. The transmission of CMGs occurs through whitefly in a circulative but non-propagative manner. It requires at least 8 h of circulation inside the whitefly before transmission into plants can occur. However, once the whitefly acquires the virus, it can remain viruliferous all its life, thus increasing the chance of viral spread for a long period of time and a longer distance. The East African cassava pandemic could be correlated to the synergism between ACMV and EACMV (Fig. 5) along with the explosion of “super abundant” whitefly populations. Recombination between different CMGs is extremely prevalent although it is not known how important this factor is in the disease spread. Recent research demonstrated that there are several whitefly biotypes infesting cassava in Africa and that these biotypes are geographically distributed.

Recent Outbreak of CMD in South East Asia

In 2016, the first report of the CMD, was published, describing the unequivocal identification of the Sri Lankan cassava mosaic virus (SLCMV) as responsible for the disease symptoms in the north east of Cambodia. Since that date, several surveys have been done in Cambodia, China, Vietnam, and Thailand, and as of January 2019, the disease was present in 10 provinces of Cambodia, 14 in Vietnam, and 7 provinces in Thailand (Fig. 6). There is no CMD case yet reported in Laos or Myanmar.

Fig. 6 Geographical distribution of cotton leaf curl geminiviruses. Cotton leaf curl disease is present in India, China, Pakistan and Philippines. The disease was first known from Pakistan and then spread to India, China and Philippines. The Chinese and Philippine's isolates are identical to each other. The dashed arrows represent direction of movement for cotton leaf curl Multan virus.

The presence of the same virus has also been reported from several locations of cassava collections in China. In 3 years, the disease reports extended from a single plantation in Cambodia to an estimated 44% of the surfaces cultivated in the whole region. The disease is transmitted in two ways: by the natural whitefly vector (*B. tabaci*, Aleyrodidae) and by the cassava cuttings, there is no transmission through the roots or the seeds. There is a very active cassava stake trade between several provinces of Cambodia and between Cambodia and Vietnam or Thailand. Although there is clearly insect transmission occurring everywhere, it is believed that currently the disease is mostly spread through cuttings. Considering the importance of cassava in the region (>55 million tons/year and >\$10 billion business) urgent action is needed to stop the spread and put CMD under control. To this effect the Global Cassava Partnership for the 21st Century - GCP21 and CIAT, organized a Regional Workshop in September 18–20, 2018, in Phnom Penh, Cambodia establishing a unique regional plan of control of CMD. This control plan lists 5 different topics; 1- Regional & National Coordination Mechanism, 2- CMD Awareness & Mitigation Extension, 3- Surveillance and Diagnostic, 4- Propagation and distribution of disease-free planting material, and 5- Varietal testing and breeding for CMD resistance. This recent emergence of CMD exemplifies the major role of international movement of infected material complemented by biological factors.

Control

In general terms, CMD can be controlled by three different ways. (1) Planting disease-free material to minimize the spread of infected material and crop losses, (2) Control of whitefly populations to delay the infection process till later growth stages, (3) Eradication of infected material to avoid the spread of infected plants through cuttings. Although CMD is known for more than a century, still the disease causes very significant losses in Africa and India. The earlier cassava breeding programs in East Africa led to the development of highly resistant germplasm against CMGs (multigenic type of resistance CMD1). Subsequently breeding programs in IITA in West Africa produced numerous CMD resistant cassava varieties between 1970 and 1990. In the 90 s another source of resistance (CMD2) of monogenic nature was identified in cassava landraces in West Africa, conferring extremely high levels of durable resistance to CMGs. SNP markers have been developed for CMD2 allowing its easy transfer to many more

genotypes of cassava. The introduction of resistant cassava germplasm in Uganda resulted in restoration of cassava yield in the late 90 s. However, due to their better processing and organoleptic properties, the farmers often prefer local susceptible landraces.

The Cotton Leaf Curl Disease in the Indian Sub-Continent

Geographical Distribution

The Cotton leaf curl disease (CLCuD) was first observed in the Multan region of Pakistan during late 1960s. The disease was limited to the surroundings of Multan until 1987. After 1987, the disease spread to the surrounding areas and appeared in epidemic form between 1992 and 1997. During early 2000, the disease spread to India, where it caused serious damage to cotton crops. Today, the disease is prevalent in Southeastern China, Philippines, Pakistan, and India. In Philippines, CLCuMuV infects hibiscus plants instead of cotton. Although there is a huge diversity among cotton leaf curl geminiviruses (CGs), the most devastating viruses are Cotton leaf curl Multan virus (CLCuMuV) and Cotton leaf curl Gezira virus (CLCuGeV-African origin). The CLCuMuV is prevalent in Pakistan, India, China, and Philippines, while CLCuGeV is present all over the Africa, wherever cotton and okra crops are grown. Indeed, CLCuGeV is now also present in Southern parts of Pakistan; however, its infection is limited on cotton crop which is dominated by Cotton leaf curl Multan virus.

The Disease Symptoms and Yield Losses

Like all other begomoviruses, the CLCuD is transmitted by whiteflies. So far there is no evidence for the seed transmission of the CLCuD. Upward or downward leaf curling, vein thickening, leaf enations and stunted growth are the main symptoms of infected plants (Fig. 7). Once the plant acquires CLCuD through whitefly inoculation, the infection is life long for the host. The infected plants remain stunted and dark green in color. Very few flowers are produced and they cannot produce fertile seeds. Over the past three decades, Pakistan had lost billions of dollars due to this disease. During the epidemic (1992–1997) Pakistan lost US\$5 billions. With the introduction of resistant varieties after the year 2000 the disease was fairly well controlled. However, a new out-break of the Burewala strain during 2004 resulted in the resistance breakdown. It was hypothesized that the Burewala strain is the most dominant virus on cotton field in Pakistan and India, however recent data showed that the Multan strain is re-emerging as a major pathogen on cotton.

Causal Agent and Disease Classification

The CLCuD is mainly caused by satellite associated monopartite begomoviruses. These satellites are known as betasatellites and alphasatellites. Both the satellites are approximately half the size of viral component and are encapsidated by the viral CP coded by the helper virus. The prevalent betasatellite is known as Cotton leaf curl Multan betasatellite (CLCuMuB). The DNA-A component of Cotton leaf curl geminiviruses alone cannot produce symptoms, until betasatellites are added. The CLCuMuB encodes a pathogenicity determinant protein. The second category of satellites associated with cotton geminiviruses are alphasatellites. They encode an alpha-Rep responsible for replication of alphasatellites and which is also a suppressor of gene silencing of the host, the natural virus defense mechanism of host. The origin of alphasatellites is considered to be from the family *Nanoviridae*. Apparently, the alphasatellites do not play an important role in the etiology of CLCuD. However, their relatively large diversity suggests that they have an important evolutionary role in disease epidemics. CLCuD is mainly caused by monopartite begomoviruses, but recently some bipartite viruses have also been reported from Pakistan. According to literature, there are at least 14 different begomovirus and one mastrevirus species, which infect the cotton crop in the Old World. CLCuMuV, CLCuGeV, *Cotton leaf curl Kokhran virus* (CLCuKoV), *Papaya leaf curl virus* (PaLCuV), and *Cotton leaf curl Alabad virus* (CLCuAlV) are frequently associated with CLCuD. However, *African cassava mosaic virus* (ACMV), *Okra leaf curl enation virus* (OLCEnV), *Tomato leaf curl New Delhi virus*

Fig. 7 Typical disease symptoms of cotton leaf curl disease in Pakistan. The healthy cotton plants have straight leaves with no curling (A). The infected plants have upward or downward leaf curling. Panel-B presents cotton infected by cotton leaf curl Multan virus, cotton leaf curl Multan betasatellite and *Gossypium darwinii* symptomless alphasatellite. The abaxial side of the infected leaf shows vein thickening and leaf like enations (panel-C).

Fig. 8 Phylogenetic tree of cotton leaf curl geminiviruses. Cotton plant has been shown infected by 14 different begomoviruses species and one mastrevirus species. These species include, *Cotton leaf curl Gezira virus* (CLCuGeV), *African cassava mosaic virus* (ACMV), *Tomato leaf curl New Delhi virus* (ToLCNDV), *Tomato leaf curl Bangalore virus* (ToLCBaV), *Papaya leaf curl virus* (PaLCV), *Okra leaf curl enation virus* (OLCEnV), *Cotton leaf curl Bangalore virus* (CLCuBaV), *Cotton leaf curl Barasat virus* (CLCuBaV), *Cotton leaf curl Kokhran virus* (CLCuKoV), *Cotton leaf curl Multan virus* (CLCuMuV), *Cotton leaf curl Alabad virus* (CLCuAaV), *Tomato leaf curl Gujarat virus* (ToLCuGuV) *Cotton yellow mosaic virus*, *Squash leaf curl virus* (SqLCV) and a mastrevirus, *Chickpea chlorotic dwarf virus* (CpCDV). Shadadpur, Burewala and Rajasthan strains are recombinants of CLCuMuV and CLCuKoV.

(ToLCNDV), *Tomato leaf curl Gujarat virus* (ToLCuGuV), *Squash leaf curl virus* (SqLCV), *Cotton yellow mosaic virus* (CYMV), *Cotton leaf curl Bangalore virus* (CLCuBaV), *Cotton leaf curl Barasat virus* (CLCuBV), *Tomato leaf curl Bangalore virus* (ToLCBaV), and *Chickpea chlorotic dwarf virus* (CpCDV- a mastrevirus) are rarely found on cotton crop (Fig. 8).

Epidemiology

Upland cotton (*Gossypium hirsutum*) was introduced in Pakistan by the East India Company from Southern Mexico. The CLCuD is not prevalent in Southern Mexico. The disease is also not seed transmissible, therefore it can be presumed that viruses causing leaf curl disease in cotton in Pakistan shifted from a local plant host to cotton. The major spread of the disease occurred when the exotic germplasm was cultivated during the late 1980s in Pakistan. Indeed, the variety S12 (imported from Texas) proved to be hyper-susceptible to the CLCuD and resulted in the explosion of the disease in a very short period of time. Even after removing the variety S12 from the field, the CLCuD epidemic continued actively. The S12 variety acted as a trigger of the epidemic but it is whiteflies that spread the disease in the country. Due to year around presence of alternative hosts for cotton leaf curl geminiviruses; the threat of CLCuD remains permanent in Pakistan and India. As a matter of fact the begomoviruses from other crops like tomato, cassava, and chickpea are also invading cotton crop. After the year 2000 a recombinant Burewala strain dominated the cotton crop in Pakistan and India. But recently CLCuMuV has re-emerged on cotton in Pakistan.

Control

CLCuD can only be controlled through the use of resistant varieties and the control of whiteflies. Recently, virus resistant cotton varieties obtained through conventional breeding were introduced. It was an immediate success but more recently the resistance was broken down by CLCuMV strains resulting from recombination with other local geminiviruses. The recombinant strains, Burewala, Shadadpur and Rajasthan played an important role in resistance breakdown. Efforts have been made to control the

CLCuD through RNAi or CRISPR/CAS9 but to date there is still no data to support the use of transgene mediated resistance in cotton. The conventional breeding still remains the first and only option in controlling the CLCuD.

Conclusion

This article is documenting the emergence of 4 major geminivirus diseases in the world in the last 30 years, namely the TYLCD and ToLCNDV on tomato, the CMD on cassava and the CLCuD on Cotton. All three examples illustrate the importance of human intervention to trigger a new epidemic, but evidently are also showing the great importance of some biological factors; the greater effectiveness of TYLCV to infect tomatoes, the capacity of ToLCNDV to capture other components and satellites, the combination of two cassava geminiviruses to synergize, and the role of a hyper susceptible cotton variety. In addition, it is also showing the major role of whiteflies in each example to carry on the epidemic to vast surfaces and for many years.

The recent global spread of ToLCNDV on various hosts is also an alarming situation. The spread of ToLCNDV and TYLCV is a global concern and concrete efforts must be done to save crops from their worldwide epidemics.

Another important concern for the world's agriculture is the Squash leaf curl virus (SLCV) spread from California to Middle Eastern countries. If the other 4 examples in this article are all Old World geminiviruses that managed to invade the rest of the world, SLCV is a New World geminivirus that successfully invaded the Middle East region. Indeed, evidences of SLCV infection on cotton also exist in Pakistan. However, it still needs authenticated experiments to prove its level of infection on cotton. The emergence of such viruses is also a future concern.

Currently it is unclear why some strains spread more rapidly than others at the global level. For example there are several strains of TYLCV, but TYLCV-Mld is more wide spread than some others. Similarly, the Uganda strain of the East African cassava mosaic virus (EACMV-UG) in Africa and the cotton leaf curl Multan virus (CLCuMuV) and its betasatellite in Asia are more wide spread than other strains. The world spread of TYLCV can be attributed to trade of tomato seedlings from the Middle East to different parts of the world. Once, the virus is introduced in a new environment, the local whiteflies can quickly acquire and spread the virus to other hosts. The CMD spread in Uganda which was triggered by the synergism between two geminiviruses and the presence of a hyper abundant whitefly, is also attributed to human migration in Africa (Rwanda in the 90 s), carrying infected cassava cuttings for further propagation over a high mountain range. The recent CMD outbreak in SEA was initiated by the import of SLCMV from the Indian subcontinent, and hugely distributed by the clonal propagation in the region. If the initial pandemic of CLCuD in Pakistan was clearly triggered by the import of a super susceptible cotton variety from the US, local whiteflies then took the relay to spread the disease in the sun-continent and to many local hosts. However, the spread of CLCuD from Pakistan to China and Philippines is more intriguing. It is plausible that Pakistan and India sharing borders, therefore whiteflies could easily transfer the disease to the neighboring countries. However, there is a mountainous region between Pakistan and China and crossing of whiteflies is not possible. The transfer of infected ornamental plants could be a reason for the spread of CLCuMuV from Pakistan to China and Philippines. The Multan strain in Philippines is identical to the one isolated in China, therefore it can be hypothesized that CLCuMuV spread from China to Philippines.

In all these examples it is clear that humans, in combination with other biological factors, have played a vital role in the spread of highly pathogenic geminiviruses. In the future, such epidemics could be avoided by more strict quarantines measures and immediate proper agricultural policy control measures.

Glossary

5'CAP The five-prime cap is a modified nucleotide at the 5' end of RNA molecules. It prevents RNA degradation by exonucleases and promotes RNA translation.

Actin filaments (microfilaments) A component of the cytoskeleton formed from polymerized G-actin monomers.

Chaperones Cellular proteins that assist in the correct folding or unfolding of proteins and in the assembly or disassembly of protein complexes.

COPI/COPII Cytoplasmic protein complexes (coatamers) that coat vesicles transporting proteins from ER to Golgi (COPII), and from Golgi to the ER (COPI).

Endosomes Membrane-bound compartments that function in the sorting and delivery of material internalized from the cell surface or destined for transport from the Golgi to the lysosome or vacuole.

ER exit sites Specialized zones of the ER engaged in COPII-mediated exit of newly synthesized proteins from the ER into vesicles for transport from ER to Golgi.

ESCRT The “endosomal sorting complexes required for transport (ESCRT)” machinery consists of cytoplasmic protein complexes involved in membrane remodeling.

GPI anchor Short glycolipid (glycosylphosphatidylinositol or glycosylphosphatidylinositol) fused to the C-terminus of a protein during posttranslational modification and tethering the protein to the outer leaflet of the PM.

Microtubules A component of the cytoskeleton composed of hollow tubes assembled from α -tubulin/ β -tubulin dimers.

Multivesicular bodies (MVB) Single membrane-bound organelles with intraluminal vesicles that mediate protein cargo transport from the trans-Golgi network (TGN) to vacuoles for degradation.

Pattern-triggered immunity (PTI) Innate immunity based on the recognition of conserved microbial signatures (patterns) by pathogen recognition receptors at the PM or in the cytoplasm.

Reticulons Proteins residing at the ER and playing a role in promoting membrane curvature.

Introduction

In order for a plant virus to infect its host systemically, it must be capable of hijacking the host's cellular machinery to replicate and move from the initially infected cell. Plant viruses require wounding, usually by insect or fungal vectors or mechanical abrasion, for an infection to begin. Once inside a cell, virus particles have to disassemble to release the viral genome which, then, can be transcribed (DNA viruses) and translated (DNA and RNA viruses) to initiate its replication and movement. Some of the viral products are required for virus movement and interact with host factors (proteins or membranes) to carry out this function. Virus movement in plants is tightly linked to virus replication and can be broken down into three distinct steps: (1) intracellular movement, (2) intercellular movement and (3) systemic movement. Intracellular movement refers to processes that allow the virus to reach plasmodesmata (PD), tiny (50 μ m in diameter) channels in the plant cell walls that connect neighboring cells, whereas intercellular movement refers to the process of virus movement through PD allowing the spread of infection between cells. By intercellular movement from-cell-to-cell and by reiteration of infection and viral genome replication and the targeting of PD in each cell, the virus finally reaches cells of the vascular system (Fig. 1). Once the virus has entered the sugar-transporting phloem sieve elements, the virus moves systemically with the flow of photoassimilates, which directs the infection efficiently to the young, sugar-importing sink tissues before also source tissues are slowly infected. Upon delivery by the phloem to a tissue distant from the original infection site, the virus exits the vasculature and resumes cell-to-cell movement via PD in the new tissue. Although virus movement generally occurs by viral exploitation of the symplasmic intercellular communication network established by PD and the connected phloem (Fig. 1), it is important to realize that some viruses, like Turnip mosaic virus (TuMV) and Rice yellow mottle virus (RYMV), also exploit the water-transporting xylem vessels, but this will not be further elaborated here.

The mechanism of virus movement in plants has been studied with a wide range of virus genera, including, but not limited to, tobamoviruses, potexviruses, hordeiviruses, comoviruses, nepoviruses, potyviruses, tombusviruses, tospoviruses, and geminiviruses. Although viruses generally move between cells with support of their Movement Proteins (MPs) (Fig. 2), the cellular pathways and host factors (proteins and membranes) used by viruses for movement show strong differences (Fig. 3). Several studies using GFP and other fluorescent proteins as visible markers have provided important insights into the dynamic changes in the subcellular distribution, accumulation, and movement patterns of viral and host proteins and helped to decipher the different processes occurring during virus infection in plant cells. The resulting observations are summarized in numerous review articles and highlight the roles of membranes and the associated cytoskeleton during virus replication and movement. This article will describe the three steps of virus movement in plants and will focus on model viruses within genera that provide the most

Fig. 1 Local and systemic virus movement in infected plants. In the inoculated leaf, viruses move cell-to cell (i) and expand the local sites of infection (a) until they reach the phloem sieve elements (SE) in the leaf vein vasculature by which they move with the flow of photoassimilates over long distance to sink tissues (ii). Upon unloading from the SE, viruses move again cell-to-cell (iii) to spread infection throughout the newly infected systemic leaves (b). Successful infection depends on compatible interactions between the virus and its host (arrows) to allow the virus to replicate its genome and to target PD (curved arrow, intracellular movement) in each cell it enters. (a) Local sites of infection by TMV tagged with green fluorescent protein (TMV-GFP). (b) a systemic leaf showing TMV-GFP as it spreads infection from the veins into the surrounding cells. BS, bundle sheath; PP/CC, phloem parenchyma/companion cell.

information on the subject. This article also considers the virus-triggered defense responses of the host that the virus must overcome to ensure its efficient cell-to-cell spread.

Intracellular Movement

Although the process of virus movement can be complex and requires support by the coordinated activity of several virus- and host-encoded proteins, many viruses achieve their movement with the help of virus-encoded 'movement proteins (MP)'. Pioneering studies with the MP of TMV and later with other MPs demonstrated that these proteins bind single-stranded RNA and modify the size-exclusion limit (SEL) of PD (Fig. 2). Moreover, upon introduction into cells by microinjection, or by transient expression using microparticle bombardment or agroinfiltration, MPs interact with PD, move between cells and may co-transport co-injected nucleic acids, thus indicating that their function is independent of infection. The ability of MP to alter PD aperture is usually correlated with the accumulation of the protein at PD. Nevertheless, plants that express the MP and are able to complement the movement function of movement-deficient TMV mutants do not show obvious growth defects, suggesting the existence of mechanisms that tightly control the ability of MP to modify PD aperture and thus prevent the continuous trafficking of signaling macromolecules between cells. Microinjection studies indeed demonstrated that the MP of TMV modifies the SEL of PD only transiently in cells at the spreading front of infection, thus confirming that MP is tightly regulated. The MP of TMV has several amino acids that are phosphorylated *in vivo* and that may play a role in regulating MP functions. Consistent with this type of posttranslational control, PD are associated with several kinases and a specific kinase, plasmodesmal-associated kinase (PAPK), was shown to specifically phosphorylate the C-terminal phosphorylation sites of MP *in vitro* and also to be active on a subset of other MPs and non-cell-autonomous plant transcription factors.

The ability of MPs to bind nucleic acids is sequence-independent, which raises the important question of how these proteins find their viral RNA cargo in infected cells. Since the MPs are produced by translation of the viral genome, they may simply attach co-translationally to viral genomes in their vicinity. Consistently, the MPs of several RNA viruses, including Tobacco mosaic virus (TMV), Potato virus X (PVX), Brome mosaic virus (BMV) or Red clover necrotic mosaic virus (RCNMV) were shown to colocalize with membrane-associated inclusions that harbor their viral replication complexes (VRC). VRCs can be highly organized structures involving membranes and cytoskeletal elements, and in which the binding of MP to viral RNA involves specific mechanisms, for

(a)

(b)

example interaction with other viral proteins, as exemplified by VRCs formed by RCNMV. Another important question is whether MPs transport viral genomes as part of subcomplexes that are derived from anchored VRCs or whether infection moves between cells in the form of mobile VRCs. Studies with TMV and other viruses have shown that VRCs develop at multiple sites in the infected cell. Moreover, VRCs can be stationary or mobile, and their subcellular formation and movement is associated with the spread of the virus. Studies with PVX have shown that VRCs can associate with PD and load replicated viral genome into PD for movement, while observations with TMV suggested that TMV spread infection by movement through PD as a wholly intact VRC. Thus, it appears that viruses develop VRCs for replication as well as for movement and that virus replication and virus movement are tightly linked processes. Movement to PD or even between cells as a VRC ensures the vicinity of MPs to the viral genome and may explain the apparent lack of evolution of any sequence specificity in the binding of MPs to nucleic acids.

Thus, how do viruses develop their VRCs and transport them to PD? TMV infection is initiated by attaching the viral RNA that entered the cell with its 5'CAP to the ER membrane. The RNA is then replicated before the virus can spread its RNA genome into adjacent cells. Time-resolved *in vivo* studies showed that TMV replication and, thus, the formation of VRCs occurs at distinct sites of the cortical ER. While some of the VRCs remain anchored at these sites and are destined for the development of ER-associated, virion-producing viral factories, other VRCs detach from their anchorage sites soon after formation and act as mobile RNA particles for intra- and intercellular transport (Fig. 3(a)). The formation of VRCs at distinct ER sites probably reflects the presence of localized mechanisms by which the virus recruits host factors and membranes for VRC formation. *In vivo* studies have shown that the membrane-associated mechanisms of VRC formation and movement are tightly associated with the cytoskeleton, thus reflecting the viral exploitation of the microtubule- and actin-dependent functions in plant endomembrane organization. The distinct sites of VRC formation by TMV overlap with sites of immobile ER at which the cortical ER-actin network intersects with microtubules. The literature suggests that such sites are attached to the plasma membrane (PM), thus potentially constituting ER-PM contact sites. In providing vertical vicinity between the PM and the ER and lateral vicinity between the ER and the associated cytoskeleton these sites may function as a cortical nexus at which actin- and microtubule-driven transport pathways for the trafficking of membranes, protein complexes and organelles converge. TMV, and potentially other viruses, may have evolved to target these junctions as sites at which membranes and host factors required for VRC formation can be recruited, concentrated, and organized. The MP of TMV has strong affinity for binding to the surfaces of both membranes and microtubules, and also interacts with microtubule-associated proteins such as tubulin dimers, γ -tubulin, and end-binding protein 1 (EB1). While microtubules may support VRC attachment and the structural stabilization of the growing VRC, the ER-associated actin network supports the recruitment of membranes and host factors to these sites with support of myosin motor proteins.

Many viruses associate with the ER for replication like TMV, but several other viruses use different locations to establish their VRCs. For example, Carnation Italian ringspot virus (CIRV) and Melon necrotic spot virus (MNSV) form factories from the outer membrane of mitochondria, whereas the tonoplast is implied to play a role in the replication of Alfalfa mosaic virus (AIMV) and Tomato mosaic virus (ToMV). Tomato bushy stunt virus (TBSV) induces the formation of multivesicular bodies (MVB) from peroxisomes and several other viruses show associations with chloroplasts. However, given that Golgi membranes, chloroplasts, peroxisomes, and also the tonoplast are tightly associated with the ER-actin network, ER membranes and associated vesicle trafficking as well as the above-described roles of the cytoskeleton in supporting membrane trafficking and anchorage may represent basic principles of membrane and host factor recruitment playing a role also in the association of viruses with these organelles.

Tight linkage between virus replication and movement is particularly important if more than a single viral RNA must be moved between cells to spread infection. Unlike TMV, RCNMV has a bipartite genome but also forms ER-associated VRCs and encodes two N-terminally overlapping replicase subunits similar to TMV. To ensure replication of RNA2 together with RNA1, the smaller replicase subunit (p27) of the replicase complex, which is associated with RNA 1, binds to RNA2 through

Fig. 2 Regulation of PD and modification by viruses. (a) PD structure and regulation. (i) PD are channels (ca. 50 μm in diameter) in the plant cell walls that provide cytoplasmic and membrane continuity between adjacent cells. Structurally they are concentric cylinders with the PM lining the cell wall and the ER forming a narrow rod called 'desmotubule' in the center. The desmotubule is linked to the PM by spoke-like extensions from all its sides. The cell wall regions surrounding the PD orifices at the PD neck regions contain deposits of callose (β -1,3 glucan). (ii) and (iii) Transport through PD occurs through the cytoplasmic space delimited by the PM and the desmotubule. This size of this space determines the size exclusion limit (SEL), thus the maximal size of the molecules that are allowed to pass from one cell to another. The SEL is regulated by two potential mechanisms. The first mechanism (ii) relies on the regulation of the callose deposits. Callose synthesis by callose synthases increases the size of the callose deposits in the cell wall, thereby narrowing the space between the PM and the desmotubule and, thus, reducing the SEL. Degradation of callose by β -1,3-glucanase has the opposite effect leading to an SEL increase. The second mechanism is based on the hypothesis that the spoke-like extensions between the desmotubule and the PM are actually formed by tether proteins that regulate their tether length in response to Ca^{2+} . PD are indeed regulated by Ca^{2+} . Elevated and reduced cytosolic Ca^{2+} levels were correlated with a decrease and increase in PD SEL, respectively. However, callose synthase holoenzyme complexes are also regulated by Ca^{2+} . Thus, further studies are needed to substantiate this model. (b) Modification of PD during viral infection. PD are associated with signaling complexes that sense the presence of pathogens and cause callose accumulation and PD closure (i). Virus-encoded MPs modify PD and allow virus movement irrespective of the physiological status of the cells by two different basic mechanisms. MPs that support virus movement in the form of a VRC/vRNP, as exemplified by the MP of TMV, modify the SEL by inducing the degradation of callose deposits, presumably by recruitment or activation of β -1,3, glucanases (ii). In contrast, tubule-forming viruses like CaMV, GFLV, or CPMV have MPs with the capacity to form a tubule-like structure within the PD channel allowing whole virion particles to move between cells. MP tubule formation depends on the interaction of MP with members of the Plasmodesmata Located Protein (PDL) family and leads to the displacement of the desmotubule and, thus, to the disruption of the ER-connectivity between cells (iii).

recognition of a Y-shaped RNA element (YRE) and also binds the complex to the membrane. Unlike the MP of TMV, the MP of RCNMV has no affinity for binding to the ER. Instead, the localization of this MP to the VRC rather depends on replicated RNA1. Interestingly, translation of MP from RNA2 depends on replicated RNA2. This way, virus movement can occur only after a functional VRC has been assembled and both viral RNAs have been replicated. The binding of the MP to the VRC is supported by the chloroplastic protein glyceraldehyde-3-phosphate dehydrogenase (GAPDH), which also binds to the smaller replicase subunit (p27). The role of chloroplastic proteins in virus replication and movement has also been noted for other viruses like TMV and Bamboo mosaic virus (BaMV). As chloroplastic proteins and salicylic acid (SA) produced in chloroplasts are implicated in the regulation of PD, it may not be surprising if chloroplasts play a yet uncharacterized role in coordinating virus replication and intercellular transport through PD. The interaction of the small subunit replicase of RCNMV with the ER and the resulting membrane perturbations involved in the formation of the VRCs are linked to interactions of p27 with components of the secretory pathway, such as ADP ribosylation factor 1 (ARF1), the target of the secretory pathway inhibitor Brefeldin A (BFA). Consistently, virus replication is inhibited by treatment of infected cells with BFA or by inhibition of the secretory pathway protein SAR1, indicating that RCNMV replication and, thus, also cell-to-cell movement depend on membrane trafficking within the COPI/COPII-dependent secretory pathway. These and many other studies indicate that the deformation and recruitment of membranes for virus replication is a rather complex process that generally involves viral interference with lipid metabolism and protein regulation, targeting and transport. Studies using heterologous expression in yeast have shown that the formation of replication vesicles by tombus- and bromovirus replicase proteins involves reticulons as well as ESCRT (Endosomal Sorting Complexes Required for Transport) and MVB (multivesicular endosome) proteins, thus implying a role of endosomal pathways and of proteins shaping the structure and curvature of membranes.

RCNMV exemplifies a relatively simple system in which only two parts of the viral genome must be replicated and moved between cells to spread infection. A more extreme case is represented by the multipartite nanoviruses, for example *Faba bean necrotic stunt virus* (FBNSV), which consists of eight genome segments. Recent studies to determine how the replication and cell-to-cell movement of eight genome segments can be coordinated led to the finding that the different segments of the virus do not occur in the same cells but in different cells. This exciting observation challenges the current view that virus replication must rely on single cells. Rather, nanoviruses, and potentially also other viruses with segmented genomes, may hijack groups of plant cells for replication and use intercellular trafficking of the virus-encoded products for functional complementation between segments and their coordinated replication and movement.

Given that virus replication and movement for many viruses are tightly connected, there must be a mechanism to determine which of the viral genomes stay in the cell to form virion progeny and which of the viral genomes are transported to PD to spread infection into adjacent cells. TMV does not require its coat protein (CP) for cell-to-cell movement and, during the time course of infection, the CP is expressed later than MP, thereby ensuring that virions are formed after the virus already spread infection between cells. The above-described studies with TMV but also studies involving other viruses like PVX and TuMV have shown that the VRC-containing membrane compartments occurring during infection are divided into small, mobile compartments associated with virus movement and larger, sessile compartments that occur later and function as viral factories that produce virion progeny. Although the two different compartments can often be observed in the same cells and may communicate with each other, the larger virion-producing compartments of TMV and also those of RCNMV and PVX rather mature after virus movement has occurred.

The mechanisms by which viruses transport their mobile VRCs to PD differ (Fig. 3) and many of the differences correlate with the mechanism by which the respective viruses modify PD to facilitate intercellular movement (see below). Because the ER membrane is continuous through PD between adjacent cells, many viruses target PD simply by transporting their VRCs along the ER membrane. However, several viruses, particularly the ‘tubule-forming’ viruses disrupt the ER continuity between cells (Fig. 2) and, therefore, depend on other, or additional, pathways to target the PD. Non-tubule-forming viruses can utilize the ER membrane because it is a fluid structure allowing embedded proteins and protein complexes to move by

Fig. 3 Examples of different PD targeting pathways used by viruses. (a) TMV forms VRCs at microtubule-associated sites of the cortical ER-actin network and targets the PD by diffusion along the ER. The targeting of the MP to PD and the spread of infection depends on class XI and class VIII myosin motors. While some early VRCs undergo movement and spread infection to new cells, other “early VRCs” stay behind and become virus factories that produce virion progeny. When class VIII myosins are inhibited, the MP accumulates in the PM and cannot enter PD. The concentration of MP within PM rafts at PD may involve endosomal recycling. (b) TuMV forms replication vesicles induced by the viral 6K2 protein that bud off from the ER at ER exit sites in a COPII-COPI-dependent manner and then move along actin filaments to reach PD. Cylindrical inclusions formed by the cylindrical inclusion protein (CI) acts as a docking point for 6K2 and for a viral protein involved in TuMV movement, called P3N-PIPO. The P3N-PIPO has the capacity to modify the SEL of PD. Thus, following docking, the cylindrical inclusion may guide P3N-PIPO and the 6K2-associated VRCs to the PD channel. (c) Tubule-forming viruses like GFLV, CaMV, and CPMV have MPs that assemble to hollow tubules that allow the cell-to-cell transport of whole virion particles. Tubule formation disrupts the ER connectivity between cells. PD targeting, tubule assembly, and virus movement depend on interaction of the MPs with members of the PDLF family at PD. The targeting of PDLF to PD depends on the ER-Golgi secretory pathway and, thus, virus movement also depends on this pathway. The cellular pathway by which GFLV targets its MP and virions to PD is not known. More is known for CaMV (but not shown here), which forms stationary and motile virion factories. The motile virion factories are transported to PD along actin filaments and deliver virion particles to the PD channel in a process involving viral proteins present in the motile complex and the MP at PD. Transport of virions through the tubules formed by the tubule-forming viruses depends on the interaction between the viral coat protein subunits of the virion and the MP within the tubule. The mechanism that drives virion transport through the tubule and whether this process may involve non-viral proteins remains to be elucidated.

diffusion. Moreover, similar to the ER-associated movements of organelles, such as Golgi complexes, mitochondria and peroxisomes, also viruses enhance the efficiency and directionality of their transport with the help of myosin motor proteins. By blocking the pathway of myosin, achieved by expression of actin-binding protein or by blocking specific myosin motors using myosin RNA silencing or expression of dominantly inhibiting myosin mutants, it was demonstrated that TMV depends on class XI and class VIII myosins for transport. Whereas class XI myosins support the transport of the TMV VRCs along the ER-actin network, class VIII myosins play a role at the PM and in the interaction of the MP with PD (Fig. 3(a)).

ER-mediated targeting to PD has also been demonstrated for many other viruses. However, while the mechanism of ER-mediated transport is rather simple for TMV, which encodes only one MP, the mechanism is more complex for viruses that encode more than one MP. For example, the rod-shaped hordei-like (hordei-, pomo-, peclu-, and beny-) viruses and potexviruses encode three MPs in overlapping open reading frames, the triple gene block (TGB). The general model for movement of these viruses involves the binding of viral RNA by TGB1 and the targeting of the TGB1:RNA complex to PD with the help of TGB2 and TGB3, transmembrane proteins that are localized to the ER. Studies using hordeiviruses, pomoviruses, and potexviruses as models demonstrated that TGB3 contains the signals for targeting specific sites on the ER, for the recruitment of TGB2, for transporting the TGB2/TGB3 complex to ER sites in proximity to the PD, and for recruitment of TGB1 to these sites. Several observations indicated that the TGB2/TGB3 complex is transported by ER-derived, motile complexes along actin filaments. Similar to the motile TMV VRCs, also these motile TGB complexes may represent VRCs. PVX, for example, replicates in association with the ER and the motile complexes contain the viral replicase as well as ribosomes and virions. At later stages of infection, the TGB proteins also colocalize with viral RNA to ER-associated replication factories that produce virions. Several lines of evidence suggest a role of microtubules in the localized formation and transport of the TGB VRCs. Thus, although many details remain to be explored, the mechanism of TGB virus movement using ER-guided movement of motile VRCs, potentially microtubules, and stationary VRCs for the formation of viral factories, appears to be similar to the ER-guided mechanism used by TMV. However, it is not always clear whether motile complexes described as “ER-derived” are still part of the ER or whether these rather represent ER vesicles that bud off from the ER. The TGB3 of *Poa semilatifolia* virus (PSV, an hordeivirus) forms motile complexes upon inhibition of the COPII-dependent ER-Golgi pathway thus indicating that PSV and potentially other TGB viruses target PD by an ER-mediated route that does not require exit from the ER. However, this is different, for example, for Turnip mosaic virus (TuMV, a potyvirus), which forms replication vesicles induced by the viral 6K2 protein that bud off from the ER at ER exit sites in a COPII-COPI-dependent manner and then move along actin filaments to reach PD (Fig. 3(b)). The requirement of exit from the ER for this virus may be linked to the specialized mechanism by which this virus targets and modifies PD for movement and which may disturb the normal ER continuity and PD function between cells. Indeed, this virus encodes a cylindrical inclusion protein (CI) that forms a highly elaborated virus-induced transport structure at PD. The CI protein acts as a docking point for 6K2 and for a viral protein involved in TuMV movement, called P3N-PIPO. P3N-PIPO has the capacity to modify the SEL of PD. Thus, following docking, the cylindrical inclusion my guide P3N-PIPO and the 6K2-associated VRCs to the PD channel.

Alternative routes for the targeting of the virus to PD are indeed required for the already mentioned “tubule-forming viruses”, which alter the inner structure of PD by forming a transport tubule assembled by MP and disrupt the ER continuity between cells (Fig. 3(c)). Viruses encoding tubule-forming MPs can be found in several virus families, such as the *Secoviridae*, *Caulimoviridae*, *Badnaviridae*, *Tospoviridae*, *Ilarviridae*, and *Bromoviridae*. One example is Cauliflower mosaic virus (CaMV), a pararetrovirus which replicates its dsDNA genome by reverse transcription of a terminally redundant RNA template. Infected cells form electron dense inclusion bodies in which the P6 protein of the virus facilitates the translation of the polycistronic viral RNA, and viral and host proteins are recruited for replication and virion assembly. In a manner similar to the virus factories formed by TMV, the inclusion bodies form in association with the ER and microtubules and can either be large, functioning as stationary “virion factories”, or small, functioning as motile complexes that target the PD. To reach PD, the motile complexes are transported along actin filaments facilitated by a protein called CHUP1 (Chloroplast Unusual Positioning Protein) that usually anchors chloroplasts to actin microfilaments and is required for the movements of chloroplasts in response to light. At the PD, the inclusion body delivers virions to the PD channel, in a process potentially involving interaction of P6 with the PD-localized MP (P1) and another P6-interacting protein called AtSRC2.2. Interestingly, the MP of the virus (P1) targets PD independently of the P6 inclusion bodies. As shown for CaMV and also for Grapevine fanleaf virus (GFLV) (Fig. 3(c)), the PD targeting by MP, efficient tubule assembly by MP and virus infection supported by MP depend on interaction of the tubule-forming MP with PD-localized proteins (PDL), a multigene protein family that localizes to PD via the ER-Golgi secretory pathway. The secretory pathway consists of interacting and highly dynamic organelles that move intracellularly with support of the actin cytoskeleton. Consistently, the PD targeting of PDL and, consequently, that of the tubule-forming MP is reduced by inhibition of the secretory pathway (e.g., with the chemical inhibitor Brefeldin A, BFA), of actin filaments (e.g., with the chemical inhibitor Latrunculin A, Lat A), or of myosins (e.g., with the chemical inhibitor 2,3 butane-dione-monoxime, BDM). Moreover, PDL and MP targeting to PD as well as GFLV movement and tubule formation by the GFLV MP depend on class XI myosins. Microtubules also play a role in this pathway, since GFLV MP tubules were shown to form at ectopic sites rather than at PD when microtubule inhibitors were present.

So far, the described mechanisms of intracellular transport involve membranes of the ER and the secretory system. However, several viruses also interact with endosomal pathways for movement. For example, TGB2 and TGB3 proteins do not move with viral RNA into adjacent cells but are recycled by endosomal membrane trafficking for further rounds of transport. Endosomal recycling may also play a role for the MP of TMV (Fig. 3(a)) and other MPs that interact with synaptotagmin A (SYTA, SYT1), one of five SYTs in *Arabidopsis*. SYTA was shown to localize to PM-derived endosomes at discrete areas at the PM, and to play an important role in endocytosis as well as in MP-mediated cell-to-cell transport. TMV movement may indeed involve a PM-associated function, since the MP showed strong accumulation at the PM when its targeting to PD was blocked by inhibition

of class VIII myosins. This observation may be related to the notion that PD contain PM rafts and that the MP of TMV and also the MPs of other viruses may be part of such rafts when present in PD. Thus, it appears conceivable that SYTA-associated endosomal recycling maintains the association of MP with membrane rafts and that myosin VIII is required to anchor the rafts at PD. Several MPs contain specific sorting motifs that are required for sorting into clathrin-coated endosomal vesicles. Mutation of such motif within the P1 MP of CaMV allowed the protein to accumulate at the PM but abolished its recruitment to PD thus again indicating that an endosomal recapture pathway plays a role in the recruitment of MPs from the PM to PD.

Intercellular Transport

PD are cytoplasmic communication channels in the cell walls between adjoining cells and play pivotal roles during plant development and in the interaction of plants with biotic and abiotic factors by allowing the cell-to-cell transport of water, metabolites, nutrients and hormones as well as of informational macromolecules such as RNAs, proteins and protein-RNA complexes. Structurally, they are concentric structures in which a cytoplasmic sleeve is delimited by the centrally located rod of the ER (the desmotubule) on one side and the PM that lines the outer diameter of the channel on the other. PD are associated with signaling components such as receptor proteins and receptor protein kinases as well as signal relaying components (*e.g.*, the already mentioned PDLs) by which the PD constantly adjust their permeability in response to developmental and environmental cues. The PM of PD contains rafts or other types of microdomains enriched in specific lipids and which bind and concentrate proteins carrying lipophilic modifications (*e.g.*, a glycosyl-phosphatidyl-inositol (GPI) “anchor”) that are enriched in PD. The SEL of PD, thus the upper limit of the size of molecules transported by PD, is determined by the degree of callose deposition in the cell wall surrounding the PD neck regions (**Fig. 2(a)**). Callose synthesis and accumulation by callose synthases in the cell wall leads to closure of the cytoplasmic compartment by forcing the PM against the desmotubule, whereas the degradation of callose by beta-1,3-glucanase opens the cytoplasmic space for intercellular transport. It has been proposed that the SEL of PD may also be regulated by proteins that tether the desmotubule to the PM and are able to regulate their tether length, and, thus, the size of the cytoplasmic space. The SEL of PD is regulated in response to Ca^{2+} waves or the sensing of pathogens. For example, one protein of the PDL family, PDL5, was shown to regulate the SEL of PD by stimulation of callose synthesis through callose synthase 1 (CalS1) and CalS8. Moreover, PDL5 is required for regulating PD permeability induced by bacterial pathogen or by accumulation of salicylic acid (SA), a hormone playing central roles in stimulating immunity against biotrophic pathogens, including viruses.

To overcome the gating of PD, the virus-encoded MPs modify PD in different ways (**Fig. 2(b)**). Whereas the MP of TMV and the MPs of probably most other viruses cause a transient modification of the PD SEL, the MPs of ‘tubule forming viruses’ assemble a hollow tubule within PD and thereby drastically alter the internal structure and function of the PD channel. The tubules formed within PD allow the cell-to-cell transport of whole virion particles, whereas viruses that modify the PD SEL move between cells rather in a non-virion form (*e.g.*, as VRCs) and may even be independent of CP, as in the case of TMV. Virion entry into tubules depends on direct or indirect interactions between the CP of the capsid and MP residues exposed in the inner tubule wall. Whereas the CPs and MPs of Cowpea mosaic virus (CPMV) and GFLV interact directly, the binding of the CP of CaMV to the MP (P1) is mediated through another viral protein (P3). The CaMV CP also binds to P6. Thus, both P6 and P3 may bind to the virion surface to assist in the transfer of virions from P6 inclusion bodies to MP (P1) within the tubule. Given that tubules are assembled by MP produced in the infected cells and have a given length, it seems likely that the tubules are dynamic structures in which MP units and associated virions that have docked to the tubule treadmill through the tubule length and are released at the distal end. However, whether tubules are indeed dynamic or rather static structures remains to be demonstrated.

The mechanism by which other MPs like that of TMV modify the PD SEL is not known. Although electron micrographs indicated that the TMV MP forms fibrillar substructures within PD cavities, it remains unknown whether these structures are functional. Other studies indicate that viruses modify the PD SEL by direct or indirect interaction with one or more beta-1,3-glucanases (GLU) and thereby direct the degradation of callose. The expression of specific GLU genes was shown to increase during infection and the efficiency of TMV movement was affected when the level of GLU expression was altered, thus confirming the hypothesis that a callose-degrading enzyme activity may regulate virus movement. Consistently, a specific glucanase, AtBG_{pap}, which localizes to PD, was identified. However, although an atbg_{pap} mutant exhibited reduced virus movement associated with increased PD-localized callose levels, it still remains to be clarified whether viruses like TMV indeed operate GLU activities for virus movement or whether they rather act by preventing infection-triggered callose synthesis. The MP of TMV and the TBG1 protein of PVX were shown to bind specific ankyrin repeat-containing proteins (TIP1-3, ANK). The tobacco homolog ANK was shown to facilitate virus movement and its co-expression with MP resulted in its recruitment from the cytoplasm to PD, in reduced callose levels at PD and increased intercellular diffusion of MP. Thus, ANK and related factors may be recruited by MP to facilitate virus movement. However, the exact mechanism through which these proteins act in virus movement remains to be further studied.

More recent studies indicated that the MP harbors a specific PD-localization signal (PLS) in its N-terminus. Interestingly, this domain is recognized by the MP-interacting protein SYTA/SYT1, which was already mentioned as a host protein required for the cell-to-cell movement of TMV and of several other viruses. Although the SYT proteins may play a role in Ca^{2+} -sensitive membrane trafficking, their similarity to mammalian synaptotagmin (E-Syt) and yeast tricalbin (Tcb) families suggests that they (also) act as membrane tethers. Thus, in addition to its function in endosomal trafficking, SYTA is now also recognized as an ER-anchored protein that tethers the ER to the PM at ER:PM contact sites and has critical functions in stabilizing the ER network. In binding MP, SYTA may play overlapping roles both in endosomal recycling of MP to maintain its enrichment at the cell periphery and also in

anchoring the MP-containing TMV VRCs to the microtubule-associated ER:PM contact sites mentioned above. Moreover, given the close proximity between the desmotubular ER and the PM within PD, it has been proposed that also the PD may represent ER:PM contact sites. In this case, SYTA may take part in the tethering of the desmotubule to the PM and thereby controlling the cytoplasmic space and, thus, the PD SEL by changing its tether length in response to Ca^{2+} (Fig. 2(a)). SYTA and other markers of ER:PM contact sites (e.g., VAP27) were found to localize to PD and to interact with PD-localized reticulons, which is consistent with this hypothesis. The finding that SYTA binds the PLS of MP and is required for the MP targeting to PD suggests that SYTA recruits or binds MP at PD. The association of MP with SYTA at PD may also imply the possibility that MP modifies PD SEL through regulating the length of SYTA tethers.

Several studies indicate that the PD SEL may also be directly or indirectly controlled by actin filaments. Consistent with a role of actin in controlling PD SEL, the MPs of TMV and of *Cucumber mosaic virus* (CMV) were shown to exhibit actin severing activity *in vitro*. Moreover, the stabilization of actin filaments by treatment with phalloidin prevented the ability of MP to increase the PD SEL *in vivo*. Although these observations suggest that MPs manipulate actin to control the PD permeability, it remains to be shown whether these MPs indeed interact with actin *in vivo* and, if so, whether the actin severing activity of these MPs occurs at PD or at other locations in the cell. Nevertheless, class VIII myosins were localized to PD, and such myosins were shown to be required for the interaction of the TMV MP with PD. Future studies may reveal whether or not PD indeed contain an actomyosin system and whether this system has a role in controlling the aperture of PD.

Virus movement through PD likely requires the activity of virus-encoded chaperones. This is illustrated by the virally encoded Hsp70 chaperone homolog (Hsp70h) of *Beet yellows virus* (BYV). This virus has a particularly large RNA genome and forms very long and flexible virions. Hsp70h is one of five virus-encoded proteins required for transport. This protein targets PD and is also found in actin-associated motile granules. Consistent with a role of the granules in intracellular transport, the targeting of Hsp70h to PD depends on intact actin filaments and class VIII myosins. The Hsp70h is a component of the filamentous capsid and its ATPase activity is required for virus cell-to-cell movement. These findings led to a model where Hsp70h mediates virion assembly and, once localized to the PD, actively translocates the virion from cell to cell via an ATP-dependent process. A role of viral proteins in plasmodesmal translocation of virus is also supported by the requirement of NTPase activities in other viral proteins for virus movement, such as in the TGBp1 helicase of PMTV and the CP of PVX. Moreover, also the helicase domains within the N-terminally overlapping replicase subunits of TMV are required for cell-to-cell movement. It seems plausible that the helicase activity found in several viruses is necessary for the remodeling of viral RNA during its passage through the PD.

As has been already mentioned, the process of virus movement through PD may also be regulated by posttranslational modifications of MP. In addition to its control by phosphorylation, the MP of TMV is also controlled by ubiquitinylation and degradation by the 26S proteasome. ER stress caused by viral replication and MP production leads to the activation of the AAA-ATPase CDC48, which binds and extracts the ubiquitinated MP from the ER and guides it into the cytoplasm for degradation. While this CDC48-dependent process of removing MP from the ER transport pathway may represent a plant defense response, this mechanism may also be part of a viral strategy to inhibit further virus movement and allow the virus to switch infection from an early phase focused on virus movement to a late phase focused on virus replication and virion production.

Systemic Transport

To achieve systemic movement, the infecting virus needs to pass through different cell types of the vascular veins until it reaches the phloem sieve elements for long-distance movement into other parts of the plant (Fig. 1). The phloem transports and distributes photosynthetic assimilates from source regions in mature leaves to sink regions that require carbon for growth and development. In addition to sugars the phloem allows the long-distance transport of many solutes, hormones, proteins and RNAs. Thus, once in the sieve element, the virus can exploit this mass flow from source to sink for its transport. The vascular veins are defined as major and minor, depending on their structure, location, branching patterns, and function. The vascular tissues of each vein, for example in tobacco, consist of cell types of the phloem, thus the sieve elements and adjacent companion cells together with phloem parenchyma cells, and cell types of the xylem, thus the xylem vessels and xylem parenchyma cells. All these cell-types are surrounded by cells of the bundle sheath which delimits the vascular tissue against the *mesophyll* tissue. Plant species differ in their strategy of loading sugars from the *mesophyll* into the phloem and this difference is reflected by the number of PD that connect the bundle sheath cells and the companion cells. In symplastic loaders, thus plant species that load sugars through PD, many PD are located at this interface, whereas in apoplastic loaders, thus plant species in which sugars are transported across the cell wall by specific transporter proteins located in the PM, only few PD are present at this interface. Since tobacco is an apoplastic loader, TMV is apparently able to find these few PD to enter the vascular tissue and cause systemic infection in this species. Moreover, whereas all species examined to date have PD between companion cells and sieve elements, PD are rather infrequent between the sieve element and either phloem parenchyma or bundle sheath cells. Thus, the sieve element is isolated from the rest of the leaf and the majority of molecules must enter the sieve element through companion cells, which therefore act as a major gatekeeper for phloem entry. Viruses use both minor or major veins to enter and exit the phloem in source and sink tissues, respectively. To reach the phloem, viruses recapitulate mechanisms of cell-to-cell movement. However, the ability to move long-distance depends on additional mechanisms. TMV, for example, moves cell-to-cell without CP but requires CP for systemic movement. Without the CP, the virus can reach bundle sheath and vascular parenchyma cells of the minor veins by cell-to-cell movement, but shows reduced accumulation in the companion cells compared to the wild type virus. This requirement of CP may

be consistent with several other findings in the literature indicating a requirement of specific interactions between virus and host factors at the boundary between different cell types. Moreover, because the phloem sieve elements are devoid of ribosomes and therefore lack the machinery to support virus replication, the viral genome may also require specific protection to reach the distant tissues. Virion particles of several viruses have been detected in the phloem, thus suggesting that virions are the most prevalent transport form of viruses in the phloem. For viruses that move cell-to-cell in a non-virion form like TMV, the exact site of virion formation is not known. While virion particles of several viruses have been detected in the PD that connect companion cells with sieve elements, the virions of CMV were only found in sieve elements thus suggesting that the virions are formed in the parietal, ER membrane-containing layer of the sieve element. Interestingly, MPs can enter the sieve element and may also be translocated to distant sites to exert an influence on PD in these regions. PD in sink tissues have larger SELs than PD in source tissues which facilitates phloem unloading. Thus, MPs that have entered the phloem stream could spread into and between cells of sink tissues and thereby prime these tissues for the subsequent export and transport of the virus.

Although long-distance movement appears to require encapsidation of the virus genome, umbraviruses like Groundnut rosette virus (GRV) do not encode a CP. Systemic movement of GRV depends on its ORF3 protein, which targets Cajal bodies in the nucleolus to recruit the nucleolar protein fibrillarin and to assemble complexes with viral RNA able to move systemically. Viroids are single-stranded, circular RNA molecules that even do not encode any protein but can nevertheless cause systemic infection. Thus, all proteins required for viroid replication and transport must be of plant host origin. The RNA is folded into a series of loops and bulges and studies on Potato spindle tuber viroid (PSTVd) and mutational analysis demonstrated that several of them are required for cell-to-cell and/or phloem entry and systemic transport. Certain phloem proteins that bind to viroids have been identified but their functional significance in viroid movement remains to be investigated.

Several viruses, for example, viruses belonging to the aphid-transmitted *Luteoviridae* family, are phloem-limited because they can enter the phloem but fail to be unloaded. The restriction of virus movement of these phloem-limited viruses usually occurs at some point outside the sieve element-companion cell (SE-CC) complex, suggesting that the limiting step in tissue invasion lies in the cell-to-cell post-phloem movement rather than in the ability to exit from the SE-CC.

Virus Movement and Plant Defense Responses

Successful systemic infection critically depends on the ability of the infecting virus to suppress the defense reactions of the plant. Replicating viruses trigger RNA silencing that targets viral RNA for cleavage and/or translational repression. RNA silencing is initiated by dsRNA produced during replication. This dsRNA is cleaved to small-interfering RNAs (siRNAs) that guide Argonaute protein-containing RNA-Induced Silencing Complexes (RISC) to further cleave viral RNA in an RNA sequence-dependent manner. Viruses encode a Viral Suppressor of RNA silencing (VSR) that binds small RNAs or interferes with another step of the RNA silencing pathway. Because plants use small RNAs and RNA silencing pathways to control gene expression, VSR activities can interfere with normal plant development and, thereby, play an important role virus-induced pathogenicity. Virus-derived and other small RNAs are mobile and may move ahead of the virus to immunize cells ahead of infection. The level and systemic spread of antiviral siRNAs is enhanced by an amplifying pathway involving RNA-dependent RNA polymerase 6 (RDR6). Enhanced production of antiviral siRNAs by RDR6 and their spread into sink tissues plays an important role in immune surveillance in meristems and derived young tissues. Viruses with weak or deleted VSR functions that are unable to suppress this amplified antiviral RNA silencing may fail to cause a sustained systemic infection. More recent studies have shown that in addition to triggering RNA silencing, dsRNAs also act as potent elicitors of Pattern-Triggered immunity (PTI), which inhibits virus propagation as well. Future studies may show how the two types of dsRNA-triggered plant host responses are coordinated during infection and whether they play synergistic roles in antiviral defense. A third layer of antiviral defense involves resistance (R) genes that cause Effector-triggered immunity (ETI) against specific viruses. ETI can lead to a hypersensitive response (HR) involving cell death, high levels of the immunity hormone SA, and the establishment of systemic acquired resistance (SAR). An important example is the tobacco N gene, which triggers an HR upon recognition of the VSR effector of TMV (the small subunits of the TMV replicase). An example for ETI without induction of an HR is provided by the RTM1 gene in Arabidopsis. The lectin-like RTM1 protein acts specifically in the phloem to restrict the long-distance movement of potyviruses, such as Tobacco etch virus (TEV), Lettuce mosaic virus (LMV), and Plum pox virus (PPV). The protein forms a complex with proteins encoded by other RTM resistance genes and likely targets the potyviral particle or a CP-containing ribonucleoprotein complex.

Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00733-0](https://doi.org/10.1016/B978-012374410-4.00733-0).

Glossary

AGOs Argonaute (AGO) proteins bind to siRNAs and cleave target RNAs in plants as part of the RNA-induced silencing complex (RISC). *Arabidopsis thaliana* has ten AGOs with specific functions, which are summarized as follows: AGO1, antiviral silencing; AGO2, DNA methylation, antiviral silencing; AGO3, antiviral silencing; AGO4, DNA methylation; AGO5, antiviral silencing; AGO6, DNA methylation; AGO7, antiviral silencing; AGO8, induction of defenses against herbivores (insects); AGO9, DNA methylation; and AGO10, antiviral silencing, but also a singular pro-viral role.

DCLs Dicer-like proteins (DCLs, RNase III-like class of proteins) cleave double-stranded RNAs (dsRNA) to generate mostly 21- to 24-nt siRNAs or miRNAs. *A. thaliana* has four DCLs with specific functions that act synergistically: DCL1, biogenesis of 21-nt miRNAs, 21-nt nat-siRNAs; DCL2, biogenesis of 22-nt siRNAs for antiviral silencing, 24-nt nat-siRNAs; DCL3, biogenesis of 24-nt siRNAs (het-siRNAs) for RdDM; and DCL4, biogenesis of 21-nt siRNAs (24-nt in rice) for antiviral silencing.

RNA drug Viruses can be controlled through cellular antiviral RNA silencing (av-RNAi) against target viral genes by spraying double-stranded RNAs (dsRNAs), which are

processed into viral siRNAs (vsiRNAs) in the applied plant cells.

siRNAs Short double-stranded RNAs ranging in size from 21- to 24-nt long generated by Dicer-like proteins (DCLs). siRNAs include: vasiRNA, virus-activated siRNAs (21- and 22-nt) derived from endogenous RNAs; vsiRNA, viral small-interfering RNAs derived from viral RNAs; nat-siRNA, natural antisense transcript-derived siRNAs (21- or 24-nt); ta-siRNA, trans-acting siRNAs targeting mostly transcription factor genes; pha-siRNA, phased siRNAs (21- to 24-nt) from endogenous RNAs triggered by a particular miRNA; piRNA, piwi-interacting RNAs (21-nt) that suppress transposable elements (TEs) in the germline (to date not found in plants); het-siRNA, heterochromatic siRNAs (24-nt) generated by DCL3; easiRNA, epigenetically associated siRNA (21-nt), derived from pericentromeric TEs due to the transient loss of RNA-dependent DNA methylation (RdDM) in sperm.

Viral silencing suppressors (VSRs) Most plant viruses encode proteins that interfere with various steps in the host RNA silencing machinery. The main mechanism can be explained by their ability to bind to dsRNAs and siRNAs. Some VSRs can target the host DNA methylation machinery to inhibit host resistance modulated by epigenetics.

Introduction

RNA silencing or RNA interference (RNAi) refers to a conserved gene silencing process mediated by short RNAs, such as short-interfering RNAs (siRNAs) and micro RNAs (miRNAs). RNAi is one of the most important mechanisms in regulating gene expression and repressing transposable elements (TEs) at the transcriptional or posttranscriptional level. Across the eukaryotic kingdom, with the exception of some yeast species including *Saccharomyces cerevisiae*, the importance of RNAi-based gene regulation has been recognized as implicated in central developmental processes, maintaining genome integrity, and resilience to biotic and abiotic environmental inputs. Furthermore, plants synthesize viral siRNAs (vsiRNAs) and virus-activated siRNAs (vasiRNAs) as a means of defense in response to viral invasion.

RNAi was first described in the free-living nematode model *Caenorhabditis elegans*. It has been considered one of the most striking biological discoveries of the 1990s. Studies on RNAi have been readily and markedly supported by the genomic and Next Generation Sequencing (NGS) era in model plants; thus, studies in the field of small noncoding RNAs have advanced at a dramatic pace. It is now clear that RNAi is diverse, and in the last decade scientific efforts have been dedicated to extending the acquired knowledge from model plants to crops. Moreover, progress is being made to combine knowledge to the mechanisms and functions or to the applications of RNAi for sustainable plant protection.

Diverse Gene-Silencing Pathways in Plants

After 30 years since the discovery of RNAi in plants, most of the related knowledge is still rooted in analyses of the model plant *Arabidopsis thaliana*. RNAi pathways in *Arabidopsis* show considerable conservation of the molecular components: (1) long perfect or imperfect double-stranded RNAs (dsRNAs) are processed by DCLs into 21- to 24-nucleotide (nt) siRNAs; (2) siRNAs can be incorporated into members of

Argonaute (AGO), the core proteins of RNA-induced silencing complex (RISC); (3) sRNAs guide RISC to target nucleic acids in a sequence-specific manner and exert their function in transcriptional or post-transcriptional gene silencing (TGS and PTGS, respectively). Across eukaryotes, plants have the most complex RNA-based control of gene expression.

PTGS is usually directed against endogenous mRNAs and includes miRNA, trans-acting siRNA (ta-siRNA), natural antisense transcript-derived siRNA (nat-siRNA), and secondary phased siRNA (pha-siRNA) pathways. Instead, TGS is directed against components of the genome, including genes, repetitive elements and TEs.

The microRNA (miRNA) pathway. miRNAs derive from specific noncoding genes denoted as MIR genes, which are transcribed by RNA polymerase II (Pol II) into long single-stranded primary transcripts (pri-miRNA). pri-miRNAs exhibit typical Pol II cap structures at their 5' termini and poly(A) tails at their 3' termini and often contain introns. pri-miRNA transcripts adopt a fold-back stem-loop structure that is processed into a mature miRNA duplex by DCL1.

The processing of pri-miRNA into the miRNA duplex has been described in detail and requires:

- Cap-binding protein 20 (CBP20) and CBP80;
- zinc finger protein SERRATE;
- dsRNA-binding protein/HYPONASTIC LEAVES 1 (DRB1/HYL1);
- Forkhead-associated (FHA) domain-containing protein DAWDLE (DDL);
- TOUGH protein (TGH);
- Proline-rich protein SICKLE (SIC); and
- RNA-binding protein MODIFIER OF SNC1, 2 (MOS2).

miRNA duplexes in nuclei undergo a maturation process. Both strands of an miRNA duplex are methylated at their 3' terminal nucleotide by the RNA methyltransferase HEN1, an S-adenosyl methionine (SAME)-binding methyltransferase; the methyl group protects miRNAs from polyuridylation and degradation at the 3' termini.

Most methylated miRNA duplexes are exported to the cytoplasm by the exportin-5 homolog HASTY. One strand of the miRNA duplex acts as a guide strand and is selectively loaded onto an AGO-containing RISC, whereas the other strand, the passenger strand (miRNA*), is discarded from the complex and rapidly degraded. Most miRNAs associate with AGO1, but specific associations with AGO2, AGO7 and AGO10 have also been reported.

miRNAs are mainly 21-nt long, and mRNA cleavage is assumed as the common approach for miRNA-mediated gene regulation in plants. In addition to regulating RNA degradation, miRNAs occasionally direct DNA methylation or inhibit translation.

miRNAs regulate endogenous gene expression during development and environmental adaptation. Thousands of miRNAs have been identified in *Arabidopsis* and other plant species. Many of them are conserved and species-specific miRNAs. The list of currently known plant miRNAs can be found in miRbase (see "Relevant Websites section"), which has been recently updated.

The trans-acting siRNA pathway. ta-siRNAs derive from *TRANS ACTING siRNA (TAS)* genes, which are transcribed by Pol II into long non-coding, single-stranded (ss)RNAs that contain one or two specific miRNA target sites. TAS RNAs are targeted by miRNA-containing AGO1 (or AGO7)-RISC, and the cleaved TAS noncoding RNA is converted into dsRNA by the suppressor of gene silencing-3 (SGS3) and host RNA-directed RNA polymerase 6 (RDR6). Subsequently, DCL4 assisted by dsRNA-binding protein 4 (DRB4) processes the dsRNA to generate a population of 21-nt ta-siRNAs in phase with the miRNA-guided cleavage site. Similar to most miRNAs, ta-siRNA duplexes are methylated by HEN1. One strand of the ta-siRNA duplex associates with RISC to guide the cleavage of target mRNAs. Some ta-siRNAs regulate juvenile-to-adult transition or, more generally, transcriptional factors involved in plant response to environmental stimuli.

The natural cis-Antisense transcript-derived siRNA pathway. In plant genomes there are many genes that can be transcribed from complementary DNA strands at the same locus. If these genes are co-expressed, they produce overlapping sense/antisense transcripts. The overlapping region initiates the biogenesis of primary 24-nt nat-siRNAs through the action of a DCL (i.e., DCL2). Primary nat-siRNAs are loaded onto a yet unidentified AGO protein to direct the cleavage of the constitutively expressed complementary transcript. In a second step, the cleaved transcript is converted into dsRNA in a RDR6- and SGS3-dependent manner. This RNA amplification step may extend beyond the overlapping region to form outer siRNAs. Further DCL1-dependent processing of the newly synthesized dsRNA will generate 21-nt nat-siRNAs in phase with the primary cleavage. Similar to miRNAs and ta-siRNAs, nat-siRNA duplexes are methylated by HEN1.

nat-siRNAs were discovered in *A. thaliana* grown under salt stress conditions. However, recent genome-wide analyses have shown the widespread existence of overlapping sense/antisense transcripts, which raises the possibility that nat-siRNAs could be major effectors of gene regulation in the plant-adaptive protection mechanism in response to either abiotic or biotic stress.

Phased-siRNAs. The ability of miRNAs to indirectly regulate gene expression through the production of secondary siRNAs is an aspect that has become more evident only recently. Indeed, mRNAs cleaved by miRNA-loaded RISC can result in dsRNA synthesis, having the targeted transcript as template (like TAS ncRNAs). The newly synthesized dsRNA molecule is primarily the substrate for DCL4 to generate a new population of "secondary siRNAs"; these have a phased pattern similar to the ta-siRNA population, with siRNAs being produced at intervals of 21-nt (or 24-nt in rice) from the miRNA cleavage site. Secondary siRNAs can have a dramatic impact on gene regulation. They can act in *cis*, amplifying the silencing effect on their own target, or in *trans*, promoting a regulatory cascade if they derive from a member of large gene families. Nucleotide-binding site-leucine-rich repeat (NBS-LRR) clusters of pathogen resistance R-genes and pentatricopeptide repeats have been found subject to such regulatory cascades.

Heterochromatic and epigenetically activated siRNA Pathways. The majority of endogenous plant siRNAs consist in 24-nt siRNAs derived from heterochromatin, i.e. chromosome regions known to be extremely poor in genes and rich in repeated sequences, DNA transposons and silent retroviruses (retro-transposons), collectively named TEs. The biogenesis of heterochromatic (het)-siRNAs depends on plant DNA-dependent RNA polymerases Pol IV (p4) and Pol V (p5) and, therefore, het-siRNAs are also known as p4/p5-siRNAs. It has been proposed that p4/p5-dependent ssRNA transcripts from heterochromatic DNA loci generate dsRNAs through the action of RDR2, in partnership with other host factors. The long dsRNAs are processed by DCL3 into 24-nt-long het-siRNAs that are, in turn, methylated by HEN1. het-siRNAs associate with AGO4, AGO6, and AGO9, which then trigger TGS at RNA-dependent DNA methylation (RdDM) targets. This results in a silent heterochromatin, the prevention of TE evasion and preservation of genome stability.

In *Arabidopsis*, pericentromeric retrotransposons and thousands of DNA transposons lose RDR2-directed RdDM during pollen grain formation. Epigenetically reactivated TEs are preferentially targeted by more than 50 miRNAs bound to AGO1. TE transcripts engage RDR6 to form dsRNAs allowing DCL4 to produce 21-nt epigenetically activated (ea) siRNAs. easiRNAs trigger cascade PTGS of TE transcripts during the reprogramming of germlines, a critical window for the plant's life cycle. However, the transient loss of RdDM in sperm is restored after fertilization by maternal 24-nt het-siRNAs; therefore, easiRNAs are recognized as playing a role in fertility and male/female compatibility.

Another class of het-siRNAs is "Needed for RDR2-independent DNA methylation" (NERD) siRNAs. NERD is a class of proteins unique to plants that contain GW motifs known to bind AGO proteins. NERD has been shown to mediate TGS by recruiting AGO2-bound 21- to 22-nt siRNAs at specific genomic sites (i.e., those unmethylated at H3 lysine 9). This alternative TGS pathway is AGO4/RDR2 independent but RDR6/AGO2 dependent.

Antiviral RNA Silencing

Viral infection in plants requires replication in the infected cells, cell-to-cell movement, and long-distance spread of the virus. To defend themselves against viral infections plants use RNAi, a mechanism that fights parasitic nucleic acids. Invasive viruses and subviral infectious entities (satellites and viroids) are triggers of antiviral (av)-RNAi, which in turn targets viral genomes or transcripts for functional inactivation. av-RNAi results in a potent response of viral restriction using components of endogenous RNA silencing pathways. The av-RNAi mechanism in plants is best understood by examining the model plant *A. thaliana*, where the main players of RNA-silencing pathways have first been identified. The four DCLs (DCL1 to 4), ten AGO proteins (AGO1 to 10) and six RDR proteins (RDR1 to 6) are involved in av-RNAi depending on the type of plant virus. Different nucleic-acid content, genome organization and replication strategies influence the av-RNAi activated by plants.

From viral long dsRNAs to viral siRNAs. Viral dsRNA. The av-RNAi machinery is first triggered by viral dsRNAs at the level of infected plant cells. The origin of viral dsRNA is diverse. Av-RNAi is differentially activated depending on viral species (Fig. 1). Endornaviruses and reoviruses possess dsRNA genomes that trigger the RNAi response. In geminiviruses, dsRNA arises from the bidirectional transcription of overlapping genes. It is a common belief that most viruses with a positive (+) or negative (−) single-stranded ssRNA genome (approximately 75% of known plant viruses) also produce dsRNAs when replicating in infected cells. However, replication occurs in specific and protected membrane niches in the plant cell that releases solely viral ssRNA. This indicates that dsRNA replication intermediates (which have not been detected *in vivo* so far) are not essential to activate av-RNAi. Conversely, viral ssRNAs are potent triggers of av-RNAi. dsRNA signals of viral ssRNAs (viral genomes, sub-genomes, and transcripts) can anneal and form dsRNA motifs, also referred to as dsRNA-like structured ssRNAs.

DCLs. Primary viral dsRNA signals, either long perfect or imperfect, are recognized and processed by DCLs associated with DRBs into 21- to 24-nt RNA duplexes called primary viral small-interfering (vsi)RNAs. *A. thaliana* DCLs (DCL1 to 4) are all involved in primary vsiRNAs. Indeed, the dsRNAs derived from cytoplasmic RNA viruses are diced by DCLs 4 and 2, while those derived from viruses establishing minichromosomes, i.e., geminiviruses and caulimoviruses, are processed by DCLs 1 and 3.

RDRs. DCLs 2 and 4 are also deputed to process RDR-dependent viral dsRNAs into secondary vsiRNAs. Indeed, combinations of RDR activities contribute to the formation of secondary dsRNAs of viral origin. Viral aberrant ssRNAs (i.e., *bona fide* truncated viral RNAs lacking 3'-polyA or 5'-MG 7-CAP) are recruited by RDRs and converted into long perfect dsRNAs. RDR-dependent viral dsRNAs are processed by DCLs into 21- to 24-nt secondary vsiRNAs, which are structurally indistinguishable from primary vsiRNAs.

vsiRNAs (viral small-interfering RNAs). 21-nt vsiRNAs are predominantly associated with positive (+) strand RNA viruses and made by DCL4 (which also produces endogenous ta-siRNAs, see above). 22-nt vsiRNAs produced by DCL2 (also involved in nat-siRNAs, see above) in the presence of DCL4 often constitute less than 20% of the total vsiRNA population in infected tissues. Infection with DNA viruses induces a more abundant production of DCL3-derived, 24-nt vsiRNAs than 21- and 22-nt vsiRNAs in *A. thaliana*. DCL1 is active in viruses with DNA genomes and only in the absence of other DCLs. Primary and secondary vsiRNA duplexes are methylated by HEN1 at the 3'-termini of 2'-OH groups, analogously to endogenous functional siRNAs (see above).

RISCs in av-RNAi. AGOs are the core components of as yet incompletely characterized RISCs (see above). AGO/RISC-mediated av-RNAi is one of the most important components of the plant's immune response against viruses. In the last decade, major efforts were dedicated to accurately describe the antiviral RISC in plants. Besides *in vivo* studies, mainly based on reverse genetic approaches, *in vitro* systems have been recently launched and appeared to be valuable tools to define and characterize AGOs with

Fig. 1 Viral RNA species targeted by av-RNA silencing in host cells. Plant viruses, including DNA viruses, have RNA states in their transcription and replication cycles. Such RNAs are mainly cleaved by Argonaute (AGO) in RNA-induced silencing complex (RISC) or subjected to translational inhibition, though rarely. Double-stranded RNA (dsRNA) viruses may be subjected directly to Dicer cleavage, but their RNA transcripts (ssRNAs) seem to be a major target of AGO because dsRNAs are suspected to be formed in viral particles. Although dsDNA and ssDNA viruses use their RNA transcripts for replication in the nucleus, such RNAs become a target of RNA silencing when translated in cytoplasm.

antiviral functions. For instance, cytoplasmic extracts of evacuated *Nicotiana tabacum* BY2 protoplasts enabled the reconstitution of av-RNAi with a defined AGO protein and (an) exogenous siRNA(s) of choice.

Both *in vivo* and *in vitro* studies have clarified that of the ten AGO proteins that were first identified in *A. thaliana*, AGO1, –2, –3, –5, –7, and –10 have antiviral RNA-silencing activity. Upon incorporation of 21-nt or 22-nt-long vsiRNAs, these AGOs exhibited cleavage activity of targeted RNAs of viral origin and the capacity to inhibit viral replication. The most highly characterized antivirally acting AGO1 and AGO2 proteins contribute to the removal of viral or subviral RNA entities by endonucleolytic cleavage of the target RNA in a vsiRNA-directed, sequence-specific manner.

AGO4 has also been shown to have antiviral activity against ssDNA viruses, such as geminiviruses, through RdDM. Indeed, geminiviral mRNAs from bi-directional transcription are subject to av-RNAi similarly to RNA viruses. In addition, upon incorporation of 24-nt-long vsiRNAs, AGO4 promotes RdDM of viral chromatin leading to transcriptional gene silencing as a potent antiviral defense.

Either length or the 5'-terminal nucleotide has a strong impact on vsiRNA sorting into specific antiviral AGOs. For example, vsiRNAs of 21- and 22-nt have a 5'-terminal U co-immunoprecipitate with AGO1, whereas those that have a 5'-terminal A

co-immunoprecipitate with AGO2. Accordingly, vsiRNAs that are effective with AGO1 contain a U at the 5'-termini, whereas those effective with AGO2 contain an A at the 5'-termini.

As for endogenous regulatory sRNAs (see above), after the incorporation of a vsiRNA duplex into an AGO protein, the passenger strand is removed while the remaining guide(g) strand directs the RISC to the cognate viral RNA.

Function of vsiRNAs as a means of symptom development. In plants infected with viruses or viroids, vsiRNAs are abundantly produced. vsiRNAs induce av-RNAi and, in some instances, symptoms in infected plants. If vsiRNAs share high degrees of sequence similarity (or complementarity) with host genes, they can oftentimes induce specific symptoms through the host RNAi pathway.

One prime example of vsiRNA-mediated gene silencing is the bright yellowing symptom on tobacco infected with a satellite RNA (Y-sat) of cucumber mosaic virus (CMV). Y-sat-derived siRNAs can induce silencing of the chlorophyll biosynthetic gene (ChlI), leading to yellow chlorosis. Viroid vsiRNAs have also been implicated for a long time in specific symptom induction, yet their molecular mechanisms remain unknown. Viroid-induced symptoms seem to be a consequence of complex physiological disorder by viroid infection where viroids interact with many host factors. However, some target gene candidates of viroid vsiRNAs have been demonstrated to be associated with symptom expression; these include, for example, the chloroplast heat-shock protein 90 (cHSP90) gene by peach latent mosaic viroid (PLMVd), the chloride channel protein-*b*-like gene (CLC-*b*-like) and 40S ribosomal protein S3a-like gene (RPS3a-like) by potato spindle tuber viroid (PSTVd).

Recent advances in NGS and computational analyses have enabled the identification of vsiRNAs *in vivo* (denoted as degradome analysis) or *in silico*, which target host genes as well as the corresponding viral RNAs. By virtue of this technical development, vsiRNA-mediated host gene silencing leading to cleavage of the target transcripts has been proposed in many virus–host interactions, *e.g.*, tobacco mosaic virus (TMV)-*Arabidopsis*, cauliflower mosaic virus (CaMV)-*Arabidopsis*, and sugarcane mosaic virus (SCMV)-maize, as well as in grapevine with multiple viral infections.

Widespread silencing of host genes and other regulatory cascades induced by viral infections. In addition to vsiRNAs, plants produce a newly discovered class of endogenous siRNAs, the 21- and 22-nt virus-activated siRNAs (vasiRNAs). The production of vasiRNAs from thousands of *Arabidopsis*-encoding transcripts is induced by at least two distinct species of RNA viruses, *i.e.*, CMV and turnip mosaic virus (TuMV). The genetic requirements of vasiRNAs are distinct from those of miRNAs, vsiRNAs, ta-siRNAs and pha-siRNAs; although they are DCL4-dependent, they require RDR1 for biogenesis. Upon incorporation into AGO2, vasiRNAs direct the widespread silencing of host genes *in cis*. The observations performed to date suggest that the widespread silencing of host genes (that largely include factors responsive to biotic and abiotic stimuli) directed by vasiRNAs plays a role in the virus resistance activated during antiviral silencing in a manner that is independent of the antiviral activity of vsiRNAs.

Unlike the unique symptom induced by Y-sat, typical symptoms such as leaf mosaics, plant stunting and abnormal leaf development may not be simply explained by a specific vsiRNA, but rather by the result of all combined molecular effects mediated by miRNAs, vsiRNAs and vasiRNAs.

Viral and Plant RNA-Silencing Suppressors

Plant virus genomes embed genetic information that is surprisingly restricted but sufficient to coordinate the entire viral life cycle including cellular infection, replication processes, invasion of the host and spread into the environment. Additionally, viral structural or non-structural proteins are programmed to protect viral genomes against av-RNAi. Such proteins are widely known as viral silencing suppressors (VSRs). Initially, sRNA binding has been shown to be the prevalent and unifying mechanism of suppression activity at least in model systems such as p19 of tombusviruses, HC-Pro of potyviruses, and p21 of closteroviruses. In the last decade, the attention devoted by the scientific community to VSRs presented an extremely rich and diverse scenario: each step or player of the plant RNAi machinery emerged as a putative target of VSRs. It was also revealed that certain VSRs have multiple targets. The VSRs and silencing players in host immunity are summarized in [Table 1](#).

Many VSRs have been described as pathogenicity determinants and, indeed, the transient or constitutive overexpression of VSRs resulted in developmental abnormalities in plants. These capacities were attributed to the binding affinities of VSRs to the respective miRNAs and, accordingly, to the alteration of miRNA accumulation and functions. However, because VSRs differentially bind to miRNAs and the important silencing players such as DCL1, AGO1 and AGO2 are regulated by miRNAs, viral symptom development is not simply explained through miRNA sequestration by VSRs. In this perspective, the influence of VSRs may have a significant impact on endogenous RNAi during the early stages of infection.

Many endogenous RNA silencing suppressors (endoRSSs) have been identified in plants. It has been well documented that stress response, differentiation and development in plants are controlled by tuning the gene expression at the right time using miRNAs. In contrast to VSRs, which are produced to destroy host RNA silencing, endoRSSs probably play a roll in breaking miRNA-mediated gene regulation to remove excessively generated miRNAs. For example, it has been demonstrated that RNA silencing suppressed by FRY1 and XRN4 would be important for shaping root architecture.

Antiviral Silencing in Crops

In some virus-host couples (woody plants, agro-ecosystems, forests) that have cohabited for long periods, av-RNAi should be more properly considered as a mechanism of surveillance ensuring the coexistence of both partners and the absence of symptoms, with

Table 1 Target sites of VSRs to promote viral infection

Target sites	VSRs examples	Remarks
<i>Direct PTGS suppression</i>		
1. Generation of siRNA/miRNA		
(1) dsRNA binding		
Long dsRNA	NSs (TSWV), 2b (CMV), P38 (TCV-CP)	
ds-siRNA	HC-Pro (poty), 2b, P19 (TBSV), 126K (TMV)	
	V2 (begomo)	
ds-miRNA	2b, 126K	
(2) ssRNA binding		
ss-siRNA/miRNA binding	AC4 (begomo), NS3 (RSV), P10 (GVA), V2	V2 binds only 24-nt ss-siRNA
(3) DCL downregulation		
DCL3, DCL4	P38	Antagonistic effect of DCL1 upregulation
DCL1	2b	
(4) DCL binding		
DRB4 (DCL4 cofactor)	P6 (CaMV)	
2. siRNA/miRNA methylation		
(1) HEN1 binding	HC-Pro	
(2) No SAM supply to HEN1	HC-Pro, bC1	bC1 is produced by bsatellite of TYLCV
3. Target RNA cleavage		
(1) AGO binding		
AGO1	HC-Pro, 2b, p38, AC2 (begomo)	
AGO2	p38	
AGO4	2b	
(2) AGO downregulation		
AGO1	HC-Pro, 2b, 126K, P38	Downregulated by miR168 to control AGO1
(3) AGO degradation		
AGO1, AGO2, AGO4	P25 (potex), P0 (polero)	
4. mRNA Translation		
(1) Ribosome binding	HC-Pro, P6	
5. Secondary siRNA amplification		
(1) RDR6 binding		
SGS3 (RDR6 cofactor)	P25, V2, P2 (RSV), CMV-CP	
(2) RDR6 downregulation	HC-Pro	
<i>Indirect PTGS suppression mediated by host factors</i>		
XRN4 (exoribonuclease 4) binding	VPg (poty), HC-Pro	Reduce antiviral function of XRN4
WEL1 activation	AC2/AL2	Enhance WEL1 exonuclease activity
rgsCaM binding	HC-Pro	Stimulate endogenous RSS
DCP2 (decapping protein 2) binding	VPg, HC-Pro	Reduce antiviral function of DCP2
vasiRNAs suppression	2b	Reduce RDR1-dependent production of vasiRNAs
<i>TGS suppression</i>		
1. DNA methylation		
(1) ADK binding	AL2/L2 (begomo)	ADK, adenosine kinase
(2) SAHH binding	HC-Pro, β C1	SAHH, S-adenocyl-L-homocystein hydrolase
(3) SAMS binding	HC-Pro	SAMS, S-adenocyl-L-methionine syntase
(4) SAM decarboxylase I binding	C2 (begomo)	SAM, S-adenocyl-L-methionine

periodical outbreaks. The study of RNA silencing and av-RNAi mechanisms in the *Arabidopsis* model system, in which genetic dissection is possible, has helped the scientific community to accelerate the identification of biological gene functions. Upfront basic research has demonstrated that the av-RNAi process holds the key to future technological applications for the sustainable production of food (see also below, in this section). Indeed, av-RNAi is also effective in crop plants, which are important from an economic standpoint. Genome sequencing projects involve all crop types, including cereals and legumes, and are being extended to minor crops, ancient varieties or to wild species as a source of resistance to plant pathogens. In addition, image-based phenotyping is extremely effective to quantify the progression of biotic impacts and to associate it to genetic traits. The time is ripe to focus on av-RNAi in crop systems allowing us to contrast viruses (as well as other pathogens and pests) with the situation in crop plants.

In *Arabidopsis*, the existence of multiple paralogs of RNA-silencing-associated proteins (*e.g.*, ten AGOs, six RDRs and four DCLs) may explain the diversification of siRNAs and gene-silencing pathways; in crops the layer of complexity is more pronounced. The majority of crop plants possesses an allopolyploid genome, as they often undergo whole-genome duplication through the recombination of two or more genomes from progenitors. Paralogs of DCL and AGO genes are often present in crops,

along with the recruitment of different accessory proteins and co-factors. This has led to functional diversification or specialization in different crops, adding layers of complexity.

In rice (*Oryza sativa* L.), only AGO1 and AGO18 expressed activity against viruses. Rice AGO1 binds vsRNA to form a RISC for resistance against rice stripe virus (RSV) and rice dwarf virus. AGO18 expression is almost undetectable, but is highly induced upon RSV infection. Overexpression of AGO18 leads to increased expression of AGO1, which together confer broad-spectrum resistance against viruses in rice.

Nicotiana benthamiana (Domin) is considered either a model plant, since it is a permissive host for many plant viruses, or a typical case of allopolyploidization which is common in the Solanaceae family (e.g., tomato, potato, eggplant, pepper). The NbAGO1 gene is duplicated, and both homeologs (generically called “duplicates” or “isoforms”) retain the capacity to be transcribed into mRNAs and mainly differ in one 18-nucleotide insertion/deletion (indel). The indel is located eight nucleotides upstream of the target site of miR168, which is an important modulator of AGO1 expression. During infection with cymbidium ringspot virus, miR168 is up-regulated; however, the indel affects miR168-guided regulation and AGO1 isoforms, both of which appear to have specific involvement in symptom development. Similarly to *N. benthamiana*, tomato (*Solanum lycopersicum* L.) has AGO1 isoforms that are differently regulated in the case of tomato yellow leaf curl Sardinia virus (TYLCSV) infection. Moreover, functional indels affect the miRNA regulation of several transcriptional factors and NBS-LRR genes during viral infection.

In tomato a large family of disease-resistance proteins with NBS-LRR has been detected, and siRNA datasets revealed the presence of a regulatory cascade affecting NBS-LRRs. The initiator of the cascade is miR482, which targets mRNAs for NBS-LRR and triggers mRNA decay as well as the production of secondary siRNAs in an RDR6-dependent manner. These secondary siRNAs target other NBS-LRR mRNAs and continue the regulatory cascade. The miR482-mediated silencing cascade is suppressed by VSRs in tomato infected with viruses, increasing expression of the mRNAs targeted by miR482 or secondary siRNAs. This process allows pathogen-inducible expression of NBS-LRR proteins and contributes to a novel layer of defense against pathogen attack and a non-race-specific plant immunity induced by viral infection. Certain secondary siRNAs from NBS-LRR upon TYLCSV infection have been recognized to target and silence tomato genes involved in the photosynthetic pathway, partially explaining the phenotype plasticity in plants as well as the appearance of yellowing symptoms in the viral pathosystem.

Viral siRNA-Mediated Antiviral RNAi in Mammalian Cells

Paralogs of Dicer and AGO genes have emerged via duplication during the evolution of all eukaryotes, including mammals. Along with the recruitment of different accessory proteins and co-factors, this process has led to functional diversification or specialization in different organisms. For example, insects encode two DCL genes – one mediating miRNA biogenesis and the other being responsible for siRNA (and vsRNA) biogenesis. Conversely, mammals only encode a single DCL gene that generates both miRNAs and siRNAs. AGO2 is responsible for siRNA-mediated target RNA cleavage in insects, whereas AGO1 mediates miRNA-dependent gene silencing. Mammals, on the other hand, encode four AGO genes, all of which are involved in miRNA-guided gene silencing; only AGO2 is capable of cleaving target RNAs to mediate siRNA-dependent RNAi.

In plants, vsRNAs mainly induce the destruction of invading RNAs, leading to antiviral immunity. This is also the case in fungi and invertebrate cells. On the other hand, because mammalian antiviral defense heavily relies on interferon-mediated production of antiviral proteins, whether RNAi can indeed induce antiviral immunity in mammalian cells (especially somatic cells) has long been a matter of debate. Although numerous studies have reported the existence of siRNA-mediated av-RNAi in mammalian cells (not necessarily somatic cells), some questions still remain unanswered. It is clear that RNAi is involved in regulating mammalian viruses by host cellular miRNAs and that TEs have been found to be regulated by TE-derived siRNAs as well as by piwi-interacting RNAs (piRNAs) in both undifferentiated and somatic cells. However, to highlight the importance of av-RNAi in mammalian cells several factors must be carefully considered; for example: (1) whether VSRs is strong enough to reduce viral siRNA levels; (2) whether VSR can suppress other types of antiviral immune response; (3) whether the components in the RNAi pathway are well expressed in somatic cells; and (4) how cellular miRNAs contribute to the observed antiviral response.

View of Applications of av-RNAi

RNA drugs: novel non-transgenic and pesticide-free approaches for plant protection. Recovery phenotype in plants was described almost 80 years ago. In brief, primary virus-infected leaves manifested severe viral symptoms, whereas the upper leaves showed attenuated symptoms and became immune to secondary infection of the same or similar viruses in terms of viral sequence. av-RNAi in plants explained the recovery phenotype and supported the notion of searching for applicative solutions to boost natural av-RNAi. Thus, plant viruses became tools to examine RNA vaccination. RNA vaccination is attractive for several reasons: (a) RNA molecules can be applied transiently, i.e., not in the context of transgenic plants; (b) sRNAs are naturally produced in plants and other eukaryotes to regulate endogenous gene expression and mediate defense responses and crosstalk among organisms, with the potential of being extended to other pathogens including fungi, pests and insects; and (c) RNA vaccination enables rapid and flexible solutions against emerging pathogen or pest resistance by simple alterations of a target sequence.

Fig. 2 Mechanism through which exogenous viral double-stranded RNAs (dsRNAs) sprayed onto leaves induce antiviral RNA silencing (from A to D). (A) dsRNA is sprayed onto leaves. (B) The applied dsRNA penetrates into cells through wound cells. (C) The dsRNA is then cleaved into short-interfering RNAs (siRNAs) by cellular Dicer-like proteins (DCLs). The siRNAs generated bind to Argonaute (AGO), which is a component of RNA-induced silencing complex (RISC), to guide AGO in targeting viral RNAs. Secondary siRNAs amplified by RNA-directed RNA polymerase (RDR) 6/DCL4 spread to neighboring cells. The transport of original dsRNA is not clear. (D) siRNAs (or dsRNAs) can be transported through phloem to induce systemic silencing in upper non-sprayed leaves.

dsRNA-based vaccination has been successfully applied against RNA viruses such as pepper mild mottle virus, tobacco etch virus, alfalfa mosaic virus, CMV, TMV, and zucchini yellow mosaic virus. dsRNAs can be easily applied to plants by spraying (Fig. 2).

Recognition of viral dsRNA by DCLs in av-RNAi produces vsRNAs to direct virus-specific resistance. In addition, viral dsRNA is being considered as a broadly conserved pathogen-associated molecular pattern (PAMP) by DCLs. PAMP involves the activation of

transcriptional signaling cascades (see vasiRNAs above and other endogenous secondary siRNAs) and could be used to confer broad-spectrum, non-specific pathogen resistance.

However, central to this application is the assumption that exogenous dsRNA does not show any non-specific side effects relating to mismatched off-target hybridization, protein binding to nucleic acids or activation of non-controlled cascades. A direct application of siRNAs ensures more specificity; the experience to date is positive and promising. Research, however, is currently focusing on aspects of stability, safety, efficiency and costs, which taken together will influence the diffusion of RNA drugs in agriculture.

Virus-induced transgenerational memory. Plant viruses can induce transient, stable, and heritable changes in gene expression without changes in genome sequences. For instance, plant-virus systems have led to the discovery and investigation of many aspects of plant epigenetics.

av-RNAi can, indeed, involve a transgenerationally inherited epigenetic modification. Thus, av-RNAi infection may induce heritable phenotypic variation that influences plant fitness in response to recurring pathogen invasions. For application purposes, its epigenetic mechanisms are far from being completely understood. However, science is not far from developing specific viral vectors that can be used to infect progenitors, conferring an inherited phenotype to the next generation. This would open the window to non-transgenic, virus-free engineered seeds.

vsiRNAs for viral metagenomics: from diagnostics to environmental studies. Given the RNAi-based plant antiviral and viral counter-defense strategies, av-RNAi often appears as a mechanism of surveillance ensuring the co-existence of both partners and the absence of symptoms. Indeed, thanks to the support of far-reaching NGS technology, we can detect new vsiRNAs as a result of av-RNAi even in non-symptomatic plants.

Viruses are incisively abundant on Earth and recognized as drivers of global processes. They also represent vast genetic and biological diversity on the planet. Viruses are obligate entities that infect the cells of living organisms, co-evolve with them and migrate from one host species to another. In plants, viruses or subviral entities can cause diseases that have serious bio-economical impacts, leading to the adoption of measures of prevention or resistance. However, in most cases, plant viruses are silent or asymptomatic in their hosts and continue to be regulators of plant gene expression, often through RNAi. Recent findings, for example, reinforce the notion that viruses are beneficial in complex ecosystems when used for specific purposes and when they do not cause diseases in agro-ecosystems. Indeed, plant viruses have been used to enhance the beauty of ornamental plants. They confer resilience under conditions of drought or cold temperatures. Genome-integrated viral forms can confer cross-protection against severe strains, support evolution by intra- or inter-specific horizontal gene transfer (plant-to-plant through virus), and can raise the fitness level of a crop in terms of seed production by attracting pollinators.

The great potential that plant viruses have in the agriculture and forestry sectors requires: (1) a greater focus on our biased notions of viruses as pathogens; (2) a deeper understanding of the mechanisms of how plant viruses regulate gene expression; and (3) closing the gap and providing insights into the composition and structure of environmental viral communities. av-RNAi includes steps of host-dependent amplification vsiRNAs, which in turn are molecular markers of viral infections. This unique feature allowed the identification of otherwise undetectable novel infectious entities in plants, present at a very low level of replication, using homology-independent approaches.

Nomenclature

AGO Argonaute
amiRNA Artificial microRNA
CP Coat protein or capsid protein
CRISPR Clustered regularly interspaced short palindromic repeats
CAS CRISPR-associated proteins
DCL Dicer-like proteins with a dsRNA-specific endoribonuclease activity
DNA Deoxyribonucleic acid
dsRNA Double-stranded RNA
miRNA MicroRNAs

mRNA Messenger RNA
nt Nucleotide
PTGS Post-transcriptional gene silencing
RdRp RNA-dependent RNA polymerase
RISC RNA-induced silencing complex
ssRNA Single-stranded RNA
RNA Ribonucleic acid
RNAi RNA interference
siRNA Small interfering RNA
ta-siRNA Trans-acting siRNA
VSR Viral suppressor of RNA silencing

Glossary

Argonaute is a family of proteins that bind small noncoding RNAs, including miRNAs and siRNAs, and are guided to RNA targets through sequence complementarity, leading to the cleavage or translation inhibition of mRNAs, including viral RNAs.

CRISPR-Cas Clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated proteins (Cas) is a prokaryotic adaptive immune system that can be leveraged for genetic material to be added, removed, or altered at particular locations in the plant genome, or to directly target viral DNA or RNA molecules.

MicroRNAs are a class of small non-coding ~21–24 nt RNAs that are involved in the regulation of gene expression at the post-transcriptional level by degrading target

mRNAs, including viral RNAs, and/or inhibiting their translation.

RNA interference is a biological process in which RNA molecules inhibit gene expression or translation by neutralizing target mRNA molecules, including viral RNAs.
Small interfering RNA is a class of 20–25 nt non-coding dsRNA molecules.

The RNA-induced silencing complex is a ribonucleoprotein complex that incorporates one strand of a miRNA or a siRNA duplex for RNAi.

Trans-acting siRNA are siRNA that repress plant gene expression through post-transcriptional gene silencing.

Transgenic plant is a plant with a genome modified by genetic engineering techniques to insert, remove or knockout genetic elements.

Introduction

Plant viruses can cause severe damage to crops by substantially reducing vigor, yield and product quality. A number of approaches are strategically implemented to mitigate the impacts of plant viruses. For example, quarantine measures and certification of seeds and propagative planting units are used to limit the introduction of virus diseases in production fields. Cultural practices, rogueing, control of vectors and cross-protection based on mild virus strains or benign satellite RNA are selected to reduce secondary spread of viruses in areas where epidemics can be problematic. However, the ideal and most effective approach to control viruses relies on the use of resistant crop cultivars. Host resistance genes have been extensively exploited by traditional breeding techniques although only a limited number of commercial crop cultivars exhibit practical resistance to viruses.

The advent of biotechnology through plant transformation, the application of the concept of pathogen-derived resistance, and the exploitation of the antiviral pathways of RNAi have opened new avenues for the development of virus-resistant crop cultivars, in particular when resistant material with desired horticultural characteristics has not been developed through conventional breeding or when no host resistance sources are known. RNAi is a conserved and RNA-dependent gene silencing process that is induced by dsRNA expression to target the cleavage of viral RNA molecules and confer resistance to virus infection via PTGS. In addition to the conventional expression of RNAi in transgenic plants to achieve virus resistance, RNAi can be triggered by the exogenous application of *in vitro*-produced dsRNA derived from viral sequences. More recently, genome editing via CRISPR/Cas has proven valuable to disrupt host susceptibility genes for the improvement of crop cultivars or directly target viral DNA or RNA for cleavage.

The past three decades have witnessed the development of numerous virus-resistant transgenic plants. Some crop cultivars engineered for virus resistance have been successfully tested in the field but only a few have been commercialized, including summer

squash and papaya which have been adopted for more than 20 years in the United States. Crop plants engineered for virus resistance offer numerous benefits to agriculture and cause extraordinarily limited, if any, hazard to the environment and human health.

A Historical Perspective on Engineered Resistance Against Plant Viruses

Genetic engineering expanded the scope of innovative approaches for virus control in crops by providing new tools to achieve resistance in otherwise susceptible plants. The first approach to confer resistance to viruses in plants resulted in the mid-1980s from the development of efficient protocols for plant transformation and the application of the concept of pathogen-derived resistance. This concept was initially conceived to achieve resistance by transferring and expressing a dysfunctional pathogen-specific molecule into the host genome to inhibit the pathogen. As a potential application of the concept, a segment of the virus' own genetic material was hypothesized to somehow protect a plant against virus infection by acting against the virus itself. The first demonstration of pathogen-derived resistance against a plant virus was with Tobacco mosaic virus (TMV) in 1986. This seminal work revealed that transgenic tobacco plants expressing the TMV CP gene showed a substantial delay in symptom development or did not display symptoms following inoculation with TMV particles. This type of resistance was known as CP-mediated resistance. It was successfully applied against numerous plant viruses.

In the early 1990s, RdRp, and then movement protein, protease, satellite RNA, defective interfering RNAs, or non-coding viral sequences were described to confer virus resistance in plants. Virus-derived transgene constructs included full-length, untranslated, and truncated coding and non-coding fragments, in sense or anti-sense orientation. It became soon apparent that more or less any viral sequence could provide some level of resistance to virus infection in transgenic plants. Remarkably, transcription of the virus-derived transgene rather than expression of a protein product was shown to be required for resistance. This pioneering work progressively led to the discovery of RNAi as a key antiviral defense of plants against viruses. Summer squash was the first virus resistant RNAi crop to be commercially released in 1996. Resistance to multiple viruses was achieved in summer squash cultivars by pyramiding several RNAi constructs derived from individual viruses.

Antiviral factors other than sequences derived from viral genomes have also been used to achieve resistance to viruses in plants. Production of antibodies, 2'-5' oligoadenylate synthase, ribosome inactivating proteins, dsRNA-specific RNases, dsRNA-dependent protein kinases, cysteine protease inhibitors, nucleoprotein-binding interfering aptamer peptides, and pathogenesis-related proteins has been reported to protect plants against virus infection.

Over the past three decades, resistance was engineered against numerous viruses with diverse taxonomic affiliations and various modes of transmission by insect vectors in many plant species and crop plants, essentially via RNAi. Further refinements of RNAi for virus resistance consisted of engineering amiRNAs to target a virus sequence and protect plants from virus infection. More recently, genome editing via CRISPR/Cas has proven valuable for engineered virus resistance by modifying host recessive resistance genes for crop improvement or directly degrading viral DNA or RNA.

Molecular Underpinnings of Engineered Resistant to Plant Viruses

Several mechanisms underlying engineered virus resistance have been described. Early studies suggested that expression of a transgene protein product seemed to be required for resistance. For example, resistance to TMV in tobacco plants was initially related to the expression level of the viral CP. Interference with an early step in the virus infection cycle, *i.e.*, disassembly of TMV particles, was hypothesized to explain CP-mediated resistance, maybe by inhibition of viral uncoating or reduction of protein-protein interactions between transgene-expressed CP and challenge virus. Resistance could be overcome by high doses of inoculum and was not very effective against virus RNA inoculation.

Next, resistance was shown to be RNA- rather than protein-mediated because untranslatable virus CP transgenes protected plants against virus infection. In addition, resistance was correlated to actively transcribed transgenes but low steady-state levels of transgene mRNA, indicating a sequence-specific post-transcriptional RNA-degradation system. RNA degradation was shown to target transgene transcripts and viral RNA with high nucleotide sequence identity. This was the first indication of the occurrence of PTGS as a manifestation of RNAi, a mechanism that inhibits gene expression in a sequence specific manner.

RNAi is a conserved eukaryotic mechanism that is critical for host defense against viruses and has become an approach of choice to engineer resistance to viruses in transgenic crops. A conserved feature of RNAi in plants is the processing of dsRNA into siRNA by DCL enzymes. Briefly, RNAi is initiated by dsRNA molecules and controlled by RISC. Long dsRNA molecules, for instance dsRNA corresponding to viral sequences, are cleaved into short dsRNA fragments of 20–25 nt siRNAs duplexes. The passenger strand of the siRNA duplexes is degraded and the guide strand is incorporated into RISC by DCL endoribonuclease proteins. Hybridization of the guide siRNA strand with a complementary RNA sequence such as a viral RNA molecule induces cleavage by AGO2, the catalytic component of RISC. This nucleotide sequence-based cleavage results in the degradation of the viral RNA target, hence resistance. Duplexes of siRNAs result from dsRNA derived from RNA virus replication, synthesis by plant RdRp, transcripts and hairpin-loop structures of ssRNAs.

Plants appear to have a set of four DCL proteins to process and generate siRNAs. DCL1 mainly processes imperfectly base-paired fold-back precursors to produce miRNAs. DCL2 generates 22 nt siRNAs and can produce secondary viral siRNAs. DCL3 generates 24 nt siRNAs that are associated with silencing of transposons and repetitive elements, and are involved in defense against DNA viruses. DCL4 generates 21 nt siRNAs that have major roles in antiviral defense against RNA viruses, and is involved in the generation of ta-siRNAs that regulate gene expression.

As an alternative to RNAi transgenic plants, exogenous application of *in vitro*-produced dsRNA to initiate RNAi via sprays or use of carrier compounds, including layered double hydroxide clay nanosheets, among other means of delivery, confers resistance to virus infection. This strategy was even shown to inhibit insect-mediated virus transmission.

To counter the RNAi plant defense, viruses have evolved RNAi-suppressor proteins called VSR. VSRs interfere at different steps of the antiviral RNAi pathways by sequestering siRNA, protecting dsRNA from degradation or interacting directly with host enzymes involved in RNAi. As a result of VSR expression, RNAi-mediated resistance is impaired.

RNAi can sometimes be unpredictable with regard to the degree of virus resistance. Different factors may be involved in deceiving levels of resistance or even loss of resistance. Nucleotide sequence divergence between a dsRNA transgene construct and cognate sequence in a virus population, the emergence of new virus strains in terms of the evolutionary dynamic of virus populations, VSRs of cognate or heterologous viruses, environmental conditions with fluctuating growing temperature during a cropping season can all affect the efficacy of RNAi at protecting plants from virus infection.

Another class of non-coding regulatory RNAs, miRNAs, has been exploited to engineer virus resistance in plants. Expression of modified miRNA precursors for which intrinsic plant specific nucleotides are replaced with virus-specific nucleotides results in the production of amiRNAs that target viral RNA sequences, resulting in resistance via RNAi. Although amiRNAs have been used for engineering resistance to a wide range of plant viruses, this strategy awaits field evaluation.

Engineered plant virus resistance can also be achieved by using CRISPR-Cas, a prokaryotic adaptive immune system which can be reprogrammed into a gene targeting technology. An RNA-guided Cas nuclease protein cleaves the substrate viral DNA or RNA at specific target sites, leading to their degradation. The specificity of the cleavage is governed by base complementarity between the CRISPR RNA and the target DNA or RNA molecule. A number of Cas proteins with sequence-specific nuclease activity have been identified to target DNA, RNA or both. Different CRISPR-Cas platforms have been successfully leveraged to engineer resistance to DNA viruses or RNA viruses *in planta*. CRISPR-Cas has also been used to knockout the host recessive eIF4E gene in cucumber and confer broad virus resistance. It will be interesting to see how this promising technology performs under field conditions.

Field Resistance and Commercial Adoption

Summer squash line ZW-20 expressing the CP gene of Zucchini yellow mosaic virus (ZYMV) and Watermelon mosaic virus (WMV), and summer squash line CZW-3 expressing the CP gene of ZYMV, WMV and Cucumber mosaic virus (CMV) were the first disease resistant transgenic plant events commercially released. Summer squash CZW-3 plants are highly resistant to mechanical inoculation of viruses in the greenhouse (Fig. 1(A)) or to aphid-mediated virus transmission in the field (Fig. 1(D)). Summer squash ZW-20 plants are highly resistant to mechanical inoculation in the field (Fig. 1(C)) or aphid-mediated virus transmission under field conditions in which no insecticides were applied to control aphid vector populations (Fig. 1(F)). Transgenic summer squash plants produce fruits of marketable quality (Fig. 1(E) and (H)) whereas most fruits of control plants are malformed and discolored (Fig. 1(E) and (G)).

Numerous transgenic crop plants such as cereal, vegetable, fruit, legume, flower, and forage crops, among others, that express RNAi constructs, virus-derived gene constructs or other antiviral factors have been developed and tested under field conditions (Table 1). A few transgenic crops engineered for virus resistance have been commercially released in the United States and the People's Republic of China (Table 1). In the United States, summer squash lines ZW-20 and CZW-3 have been commercialized in 1996. Several squash types and cultivars have been developed by crosses and back crosses with the two initially deregulated lines. Papaya expressing the CP gene of Papaya ringspot virus (PRSV) has been deregulated and commercialized in Hawaii in 1998. PRSV-resistant papaya was the first transgenic fruit crop to be commercially released in the United States. PRSV-resistant transgenic papaya cultivars are also commercialized in the People's Republic of China. Several potato expressing the RdRp gene of Potato leafroll virus or the CP gene of Potato virus Y were deregulated in 1998 and 2000. However, soon after their release, these potato lines were withdrawn from the market.

Benefits of Virus-Resistant Transgenic Plants to Agriculture

Virus-resistant transgenic plants offer numerous benefits to agriculture, particularly in cases where no genetic source of resistance has been identified or host resistance is challenging to transfer into elite cultivars by traditional breeding approaches due to genetic incompatibility or linkage to undesired traits. In such cases, engineered resistance may be the only viable option to develop virus-resistant cultivars. Engineered resistance may also be the only approach to develop cultivars with multiple sources of resistance by pyramiding several RNAi constructs.

Benefits of virus-resistant transgenic plants are of economic importance because yields are increased and quality of crop products improved. For example, the adoption of PRSV-resistant transgenic papaya cultivars resulted in a similar production level than before PRSV became epidemic in Hawaii, providing a steady source of income to growers. Benefits are also of epidemiological importance because virus-resistant transgenic plants limit virus infection rates by restricting challenge viruses, reducing their titers, or inhibiting their replication and/or cell-to-cell or systemic movement. Therefore, lower virus levels reduce the frequency of acquisition by vectors and subsequent transmission within and between field sites. Consequently, virus epidemics are substantially limited. In addition, benefits of virus-resistant transgenic plants are of environmental importance because chemicals directed to

Fig. 1 Reaction of transgenic summer squash ZW-20 expressing the CP gene of Zucchini yellow mosaic virus (ZYMV) and Watermelon mosaic virus (WMV), and of transgenic summer squash CZW-3 expressing the CP gene of ZYMV, WMV and Cucumber mosaic virus (CMV) to virus infection. (A) Resistance of transgenic CZW-3 to infection by CMV, ZYMV and WMV (upper right), and susceptibility of conventional plants to single infection by CMV (lower right), ZYMV (upper left) and WMV (lower left); (B) Fields of transgenic ZW-20 (foreground) and conventional summer squash plants (background) surrounded by a border row of mechanically-inoculated non-transgenic plants; (C) Transgenic ZW-20 (right) and conventional (left) plants subjected to mechanical inoculation of ZYMV and WMV; (D) Transgenic CZW-3 (right) and conventional (left) plants mechanically inoculated with ZYMV, WMV and CMV; (E) Close-up of a fruit of transgenic ZW-20 (extreme left) and fruits of conventional summer squash plants; (F) Transgenic CZW-3 (middle and right rows) and conventional (left row) summer squash subjected to aphid-mediated inoculation by ZYMV, WMV and CMV; (G) Fruit production of conventional summer squash under conditions of infection by ZYMV and WMV; and, (H) Fruit production of transgenic summer squash ZW-20 under conditions of infection by ZYMV and WMV.

control virus vector populations are reduced or not necessary. Restricting the reliance on chemicals directed to arthropod, fungal and nematode vectors of plant viruses is important for sustainable agriculture. Finally, benefits of virus-resistant transgenic plants are of social importance. In Hawaii, growing papaya was not viable anymore prior to the adoption of PRSV-resistant transgenic papaya despite huge efforts to eradicate infected trees in order to limit the propagation of the virus. The impact of PRSV was so severe that some growers abandoned their farms and had to find new jobs to secure an income. PRSV-resistant transgenic papaya saved the papaya industry and strengthened the social welfare of local communities in Hawaii.

Table 1 Examples of virus-resistant transgenic crops that have been tested in the field or commercially released. This list is not exhaustive

<i>Crop category</i>				
<i>Crop common name</i>	<i>Crop scientific name</i>	<i>Resistance to virus</i>	<i>Genus</i>	<i>Family</i>
<i>Cereals</i>				
Barley	<i>Hordeum vulgare</i>	Barley yellow dwarf virus	<i>Luteovirus</i>	<i>Luteoviridae</i>
		Wheat dwarf virus	<i>Mastrevirus</i>	<i>Geminiviridae</i>
		Barley stripe mosaic virus	<i>Hordeivirus</i>	<i>Virgaviridae</i>
Canola	<i>Brassica napus</i>	Turnip mosaic virus	<i>Potyvirus</i>	<i>Potyviridae</i>
Maize	<i>Zea mays</i>	Maize dwarf mosaic virus	<i>Potyvirus</i>	<i>Potyviridae</i>

Environmental and Human Health Safety Issues

The insertion and expression of virus-derived genes or gene fragments in plants has raised concerns on their environmental and human health safety. Potential risks relate primarily to the occurrence and outcomes of heterologous encapsidation, recombination, gene flow, toxicity and allergenicity. It is important to keep in perspective that these three phenomena did not arise with transgenic plants expressing viral genes or gene fragments; they occur in conventional plants too. Therefore, it is critical to determine if they occur in transgenic plants beyond baseline events in conventional plants.

Heterologous encapsidation refers to the encapsidation of the genome of a challenge virus by CP subunits expressed in a transgenic plant containing a viral CP gene. Since the CP carries determinants for vector specificity, among other features, the properties of field viruses may change. Therefore, it is conceivable that an otherwise vector non-transmissible virus could become transmissible through heterologous encapsidation and infect otherwise non-host plants. Extensive work has shown that heterologous encapsidation in transgenic plants expressing virus CP genes should be considered negligible in regard to adverse environmental effects, given this phenomenon is known to occur in conventional plants subjected to mixed virus infection. It should also be kept in perspective that any change in vector specific is a single generation rather than a permanent event because they are not perpetuated in the virus genome progeny.

Recombination refers to template switching between viral transgene transcripts and the genome of a challenge virus. Resulting recombinant viruses may have a chimeric genome consisting of a segment from the challenge viral genome and another segment from viral transgene transcripts. It is argued that recombinant viruses may have identical biological properties as their parental lineages or new biological properties such as changes in vector specificity, expanded host range or increased pathogenicity. Since recombination alters the genome of challenge viruses, new properties of chimeric viruses will be stably transmitted to and perpetuated within the virus progeny. Comprehensive laboratory studies documented the occurrence of recombination in transgenic plants expressing viral genes. However, extensive field studies revealed a limited significance of recombination in transgenic plants expressing viral genes in regard to adverse environmental effects. This is because the stringency of selective pressure applied to the challenge virus is a critical factor in the recovery of recombinant viruses. Conditions of high selective pressure enhance the creation of recombinant viruses. In contrast, limited, if any, recombinant viruses are found to detectable level

under conditions of low or no selective pressure. The latter conditions prevail under field conditions in which plants are infected by functional, not defective, viruses.

Gene flow refers to the pollen-driven movement of transgenes from a virus-resistant transgenic plant into a non-transgenic compatible recipient plant, for example, a free-living relative. Hybrids resulting from gene flow can acquire and express virus-derived transgenes, and become resistant to the corresponding viruses. Subsequently, plants acquiring viral resistance traits can have a competitive advantage, exhibit increased fitness and eventually become more invasive. Movement of viral transgene constructs through pollen flow has been documented from a few virus-resistant transgenic crops, including summer squash, into free-living relatives under experimental field conditions. Hybrids between transgenic and free-living plants exhibited increased fitness under conditions of intense disease pressure. In contrast, under conditions of low disease pressure, no difference was observed between hybrids and free-living plant in terms of growth and reproductive potential. It is important to keep in perspective that gene flow with virus-resistant transgenic plants should not be perceived riskier than the equivalent situation with virus-resistant conventional plants.

Safety assessment studies on human health have documented no evidence of toxicity and allergenicity in crop cultivars engineered for virus resistance or food derived thereof. To fully grasp the significance of these findings, it is critical to recognize that plant virus proteins or sequences are not known to code for toxins, create new allergens or change the expression of endogenous proteins to produce allergens. In addition, foods derived from virus-resistant transgenic summer squash and papaya have been consumed by millions of people for more than 20 years, with no reported ill effects or legal cases related to human health.

So far, there is no compelling evidence to indicate that transgenic plants expressing virus genes or gene fragments increase the frequency of heterologous encapsidation, recombination, or food toxicity and allergenicity beyond background events. Similarly, there is little evidence, if any, to infer that transgenic plants expressing virus genes or gene fragments alter the properties of existing virus populations or create new viruses that could not arise naturally in conventional plants subjected to multiple virus infection. Finally, consequences of gene flow should be assessed on a case-by-case approach to make sound decisions on the safe release of crop cultivars engineered for virus resistance.

Conclusions

Virus diseases remain a huge problem for a sustainable and efficient agriculture. Engineered resistance via RNAi and genome editing has expanded the scope of innovative approaches for the management of virus diseases by providing new tools to develop resistant crop cultivars and increasing opportunities to implement effective and sustainable management strategies. The past three decades have witnessed an explosion in the development of virus-resistant transgenic plants. Lessons from field experiments and commercial release of virus-resistant summer squash, papaya, and potato have demonstrated that benefits outweigh by far risks to the environment and human health. Nonetheless, despite remarkable progress, less than a handful of virus-resistant transgenic crops have been commercially adopted. A timely release of new virus-resistant transgenic crop cultivars would be desirable because viruses continue to be devastating.

This is an update of P. Moffett, D.F. Klessig, Plant Resistance to Viruses: Natural Resistance Associated with Dominant Genes, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00469-6.

Nomenclature

AGO Argonaute protein
Avr Avirulence
CC Coiled-coil structure
DCL Dicer-like
dsRNA Double-stranded RNA
EDS Enhanced disease susceptibility
HR Hypersensitive response
LRR Leucine-rich repeat
MP Movement protein
mRNA Messenger RNA
NB-ARC Nucleotide binding adaptor

NLRC Nod-like receptor
nt Nucleotide(s)
PAD Phytoalexin deficient
R Dominant resistance
RDR RNA-dependent RNA polymerase
RISC RNA-induced silencing complex
RITS RNA-induced transcriptional silencing
RNAi RNA interference
TIR Toll and interleukin receptor
VIGS Virus-induced gene silencing
VSR Viral suppressor of RNA silencing
ZAR Hopz-activated resistance

Glossary

Apoptosome An oligomerized form of animal R proteins, for example of APAF1 and CED4, leading to activation of apoptotic initiator caspases.

Avirulence gene Any pathogen gene whose protein product induces a resistance response in a plant possessing a matching resistance gene, thereby rendering the pathogen unable to establish an infection.

Gene-for-gene resistance A genetic paradigm whereby the outcome of a plant–pathogen interaction is determined by the genotype of both organisms. Plant disease resistance proteins confer resistance to pathogens possessing a corresponding avirulence gene.

Hypersensitive response A type of programmed cell death induced by a resistant plant in response to pathogen infection. Cell death is normally contained to infected cells.

Inflammasome An oligomerized form of animal R proteins, for example of NLRC4, leading to activation of inflammatory caspases.

NB-LRR protein Plant disease resistance proteins containing a central nucleotide-binding domain (NB) and C-terminal leucine-rich repeat (LRR) domain. Also known as NBS-LRR, NB-ARC-LRR or NLR proteins.

Resistance gene Plant genes which confer resistance to specific pathogens. Resistance genes confer resistance to pathogens possessing a corresponding avirulence gene.

Resistosome An oligomerized form of activated plant NB-LRRs, recently identified for ZAR1, bearing structural resemblance to animal apoptosomes and inflammasomes.

RNA interference A broad antiviral defense system used by plants, animals, and fungi. It recognizes double-stranded RNA as a cue of viral presence and induces degradation or silencing of viral transcripts or genomes.

Virulence gene Any pathogen gene whose function contributes to increased pathogen proliferation or disease symptoms on an infected plant.

Introduction

Host plants possess polymorphic resistance to different strains or races of pathogens, which is controlled by a single gene. Disease resistance controlled by recessive genes is often a passive form of resistance wherein the pathogen is unable to utilize the host-cell machinery. Dominant resistance (*R*) genes in plants appear to actively recognize the presence of specific pathogens and initiate responses to counteract infection. Usually, this involves a type of programmed cell death termed hypersensitive response (HR). However, this resistance is dependent on the pathogen possessing a corresponding gene that matches the *R* gene. These pathogen avirulence (*Avr*) genes are also dominant over their cognate virulent (*avr*) alleles. Since the outcome of an attempted infection is dependent on the genotype of both host and pathogen, this phenomenon is known as gene-for-gene resistance. Gene-for-gene resistance was first described over 60 years ago, with the discovery of various *R* genes against specific races of flax rust, caused by the fungus *Melampsora lini*, among different flax genotypes. Ever since, gene-for-gene resistance has been observed for many plant pathogens including fungi, oomycetes, bacteria, insects, nematodes, and viruses.

R Gene Products

R genes have been genetically characterized for many years and have been incorporated into breeding programs of multiple crops. To study the structure and function of the *R* gene encoded proteins, numerous *R* genes have been cloned. These proteins belong to a small number of protein classes including transmembrane proteins possessing extracellular leucine-rich repeat (LRR) domains as well as a small number of intracellular serine/threonine kinases. The most abundant class of *R* genes encodes intracellular proteins containing a central NB-ARC (nucleotide binding adaptor shared by APAF-1, certain *R* gene products, and CED-4) domain as well as a C-terminal LRR domain. Additionally, these proteins contain an N-terminal signaling domain, either displaying homology to the Toll and interleukin receptors (TIR domain) of animals or containing a coiled-coil structure (CC). These proteins are often denoted as CC-NB-LRR or CNL, and TIR-NB-LRR or TNL, collectively known as NB-LRR or NLR. Here, CC-NB-LRR and TIR-NB-LRR, collectively NB-LRR, will be used.

Sequencing projects have revealed that plant genomes contain large numbers of genes encoding NB-LRR proteins. For example, the *Arabidopsis* genome contains 149 such genes, whereas the cassava genome encodes 327, 99 of which are lacking an LRR domain. The polymorphic nature of host plant resistance is attributed to the polymorphic NB-LRR gene loci, with different alleles recognizing different pathogens or pathogen races. Furthermore, the proteins encoded are highly divergent both within and between species, presenting a large potential for recognition of pathogen diversity. *R* genes recognizing a specific pathogen could be identified by testing many genotypes of a certain species. For crop species, resistance sources are often identified in, and introgressed from, wild relatives.

Molecular studies have shown that recognition specificity is in most cases determined by the LRR domain of NB-LRR proteins. In certain cases, this could be demonstrated through swapping of LRR domains between two similar NB-LRR proteins. Correspondingly, the LRR domain is the most polymorphic region of NB-LRR proteins. Bioinformatics studies have suggested that the LRR domains are under diversifying selection, suggesting that this class of *R* genes is under selective pressure. There do not appear to be any obvious features that distinguish between those *R* genes that recognize, for example, bacteria versus those that recognize viruses. Within *Arabidopsis*, for example, the *HRT*, *RCY1* (*Resistance to CMV* (Y)), and *RPP8* genes are alleles of the same locus, but confer resistance to Turnip crinkle virus (TCV), Cucumber mosaic virus (CMV), and the oomycete *Hyaloperonospora parasitica*, respectively. Similarly, in potato, gene-duplication events have led to highly similar gene paralogues, *Rx1* and *Gpa2*, which confer resistance to Potato virus X (PVX) and to the nematode *Globodera pallida*, respectively. Additionally, PVX can be engineered to express a bacterial *Avr* gene and a plant expressing the corresponding NB-LRR gene will be resistant to the recombinant virus. Thus, most NB-LRR genes probably have the potential to evolve specificity to a variety of different pathogen types, allowing for maximum adaptability. As such, the mechanisms of recognition and initiation of disease-resistance responses are likely to be similar between *R* proteins that recognize viruses and *R* proteins that recognize other types of pathogens.

R Gene Responses to Viruses

Many different types of pathogen proteins are either synthesized in the host cell by intracellular pathogens (viruses) or delivered into the cytoplasm by the various secretion systems of bacteria, fungi, or oomycetes. Here, they can be recognized by NB-LRR proteins. In absence of a corresponding *R* gene, *Avr* proteins generally act as virulence factors, protect the pathogen from host defense responses, actively inhibit host defenses, or are involved in replication of the pathogen. Pathogen *avr* alleles can overcome *R*-gene-mediated resistance either by mutation or by elimination of the appropriate *Avr* gene. However, this often leads to a loss of fitness. Given their small genomes, this is particularly acute for viruses as most viral genes are crucial for viral fitness and often have multiple functions. An overview of cloned NB-LRR genes of which the *Avr* determinant has been identified is presented in Table 1. Anti-viral NB-LRR genes that have not been cloned yet or have an unknown elicitor can be found in recent extensive reviews, for example by de Ronde *et al.*

One of the most studied antiviral *R* genes is the *N* gene. It was introduced into commercial tobacco cultivars from *Nicotiana glutinosa* via interspecific crosses as a means of conferring resistance to tobamoviruses, primarily Tobacco mosaic virus (TMV). The *N* gene was among the first *R* genes to be cloned and encodes a typical TIR-NB-LRR protein. Like several TIR-NB-LRR-encoding genes, the *N* gene produces two different transcripts via alternative splicing, one encoding the full protein and a shorter version encoding a protein lacking the LRR domain. The role of these truncated proteins is unclear; plants transgenic for versions of the *N* gene that cannot produce both splice forms are compromised in their resistance to TMV. The *N* gene confers resistance against a wide range of tobamoviruses, with the exception of a virus originally designated TMV-ob and renamed Obuda pepper virus (ObPV). The *Avr* effector of the *N* gene resides in the TMV viral replicase protein, as demonstrated through gene swaps between TMV and ObPV. Expression of a helicase domain (p50) of the replicase is sufficient to induce HR in *N* plants. The HR induced by *N* in response to TMV is visible as small necrotic lesions at the site of infection. In this case, the virus is able to replicate to a limited degree, spreading to cells surrounding the initially infected cell before the onset of cell death. Initiation of HR requires only the presence of a matching pair of *R* and *Avr* proteins. In the past decades it has become evident that cell death caused by HR does not equate the resistance response. Follow-up studies indicated that the *N* gene based antiviral response leads to a translational arrest of viral transcripts by a process involving Argonaute 4 (AGO4), ultimately preventing virus accumulation and spread. Additionally, in cases of HR-induction with *Rx1*, this response can be knocked out without affecting *Rx1*-mediated resistance against PVX. Similar observations have been made by others and suggest that the actual resistance response is different from an HR, although often both are triggered. It follows that HR continues to serve as a valuable indication of NB-LRR mediated resistance.

Table 1 Overview of cloned and characterized antiviral NB-LRR genes. Columns list the plant species in which the *R* gene has been introgressed (plant), the domain facilitating oligomerization, the viral Avr determinant and the resistance response

<i>R</i> gene	Encoded protein	Plant	Homo-oligomerization domain	Virus	Avr determinant	Resistance response ^a
N	TIR-NB-LRR	Tobacco	NB-ARC	Tobamoviruses	Helicase/p50 subunit	HR
Rx1	CC-NB-LRR	Potato	— ^b	PVX	CP	ER
Rx2	CC-NB-LRR	Potato	ND	PVX	CP	ER
Sw-5b	CC-NB-LRR	Tomato	NB-ARC	Tospoviruses (TSWV, GRSV, TCSV)	NSm	ER, HR
HRT	CC-NB-LRR	Arabidopsis	ND	TCV	CP	HR
RCY-1	CC-NB-LRR	Arabidopsis	ND	CMV	CP	HR
Tm2	CC-NB-LRR	Tomato	ND	Tobamoviruses	30 kDa MP	ER
Tm22	CC-NB-LRR	Tomato	ND	Tobamoviruses	30 kDa MP	ER

^aCertain resistance genes condition more than one type of response depending on viral isolate, genetic background, or environmental conditions.

^bRx1 was found to heterodimerize with RanGAP2, there is no evidence for homodimerization.

Note: ND, not determined.

For some plant-virus interactions, HR is observed although a strict gene-for-gene relationship has not been defined due to a lack of variability in either the host or the pathogen. For example, eggplant undergoes a typical HR response when inoculated with tobamoviruses. A compatible interaction was not found either because the corresponding *R* gene is present in all cultivars of eggplant, or because not enough genetic material has been tested. This raises the possibility that some cases of non-host resistance, where all accessions are resistant to all isolates of a pathogen, may in fact be controlled by the same mechanisms as gene-for-gene resistance.

Aside from the typical HR, an interaction between an Avr determinant and an *R* gene encoded protein can result in two other comparable responses: extreme resistance (ER) and systemic necrosis (SN). ER is broadly defined as a lack of visible response to virus infection. In an ER response there is no necrosis and little or no virus accumulation can be detected. SN is caused by the capability of the virus to evade the initial resistance response and spread to systemic tissues. However, the accumulation of virus here eventually leads to the initiation of cell death. This response is not sufficient to contain the virus, causing a trailing HR that eventually leads to collapse of the plant. The differences between these three responses, HR, ER, and SN, are suggested to be quantitative rather than qualitative, as illustrated by the following examples.

The *Rx1* and *Rx2* CC-NB-LRR genes in potato confer an ER response to PVX, upon recognition of the same domain of the coat protein (CP). However, co-expression with the PVX CP results in an HR. The ER responses induced by *Rx1* and *Rx2* are thus not qualitatively different from HR, but rather eliminate the source of the Avr protein before it accumulates to HR inducing levels. Varying recognition efficiency of an NB-LRR protein between Avr effectors of different viral strains can result in a differential response, as in the case of Sw-5b. This tomato CC-NB-LRR recognizes the NSm protein of Tomato spotted wilt virus (TSWV), Tomato chlorotic spot virus (TCSV), and Groundnut ringspot virus (GRSV). Depending on the strain used, either HR or ER responses can be seen. The *Arabidopsis* CC-NB-LRR gene *HRT* (HR to TCV) recognizes the TCV CP, but in roughly 10% of cases the virus escapes the initial HR and replicates in systemic tissue, leading to SN. In absence of a second recessive gene, *mt* (regulates resistance to TCV), this effect is much more pronounced. Although as of yet unidentified, this gene is expected to elevate *HRT* transcript levels in the highly resistant line Di-17. Additionally, the *Rsv1* gene of soybean recognizes the viral Avr determinant of different Soybean mosaic virus (SMV) strains with varying efficiency, leading to ER, systemic infection, or SN, depending on the viral isolate. In the case of the *I* TIR-NB-LRR gene in bean, defense responses range from ER to HR to SN depending on the potyvirus isolate. The defense response is both dependent on temperature and has a gene dosage effect. At 23°C plants homozygous for the *I* gene (*I/I*) confer ER to Bean common mosaic virus (BCMV), whereas heterozygous plants (*I/i*) confer an HR-type of resistance. At 34°C, SN is seen on *I/i* plants, but to a lesser degree on *I/I* plants.

Thus, the different responses to viruses by resistant plants likely represent a continuum of quantitatively different responses. The degree of response can be modulated by the relative efficiency of recognition of the Avr determinant, *R* gene dosage, temperature, and genetic background.

Mechanisms of Recognition

Given the relatively straightforward genetic relationship between *R* and *Avr* genes, it was originally proposed that this might represent a receptor–ligand interaction. Since LRR domains often act as protein–protein interaction domains, it was proposed that the variable LRR domains of NB-LRR proteins would bind to different Avr proteins and this binding would activate defense responses. However, initial difficulties in demonstrating such interactions led to the formulation of indirect models of recognition. The guard hypothesis states that, since many *Avr* genes are also virulence genes, *R* proteins would ‘guard’ their cellular targets. The pathogen effector would modify cellular proteins, which is in turn detected by *R* proteins. Several examples of indirect recognition have been studied. For example, when expressed in *Pseudomonas syringae*, the Avr proteins AvrB and AvrRpm1 are both recognized

by the *Arabidopsis* CC-NB-LRR protein resistance to *P. syringae* pv *maculicola* 1 (RPM1). RPM1 interacts with rpm1 interacting protein 4 (RIN4), a cellular protein which in turn can interact with both AvrB and AvrRpm1. This latter interaction is thought to activate the RPM1 protein. The Avr protein AvrRpt2 from *P. syringae* is a cysteine protease and is recognized by the *Arabidopsis* CC-NB-LRR protein resistant to *P. syringae* 2 (RPS2). RPS2 also binds RIN4 and becomes activated when RIN4 is cleaved by AvrRpt2. In the absence of RIN4, for example through genetic ablation, RPS2 is constitutively activated. In this case, RIN4 thus appears to function as a negative regulatory protein.

At the same time, however, there is some indication that certain Avr/R protein pairs may interact directly. Yeast two-hybrid studies have shown Avr proteins interacting with the rice Pi-Ta, *Arabidopsis* RRS1 (resistant to *Ralstonia solanacearum* 1), and the flax L NB-LRR proteins which confer resistance to rice blast fungus, *R. solanacearum*, and flax rust, respectively. Direct interactions have also been reported between the viral R protein N and its cognate elicitor p50, surprisingly mediated by the TIR domain of N. However, a great deal about these interactions remains unclear, such as whether the other Avr proteins interact with the LRR domain, another part of the protein, or a combination thereof.

Two traits desired by plant breeders related to recognition are broad-spectrum resistance and durability. Often, *R* genes are deployed that provide good resistance but are quickly overcome by new strains of a pathogen. The durability of an *R* gene may be affected by different aspects of the pathogen such as dispersal rates and mechanisms, occurrence of sexual reproduction, and variable repertoires of virulence factors. However, since viruses cannot dispense with any of their limited number of genes, overcoming resistance must occur through sequence changes. Several cases have been studied where the virus *Avr* gene has mutated to a point it is no longer recognized by the corresponding *R* gene. However, this often results in a loss of viral fitness due to the detrimental effect of these mutations, as illustrated by the examples below.

The CC-NB-LRR encoding genes *Tm-2* and *Tm-22* have been introgressed from different *Lycopersicon peruvianum* accessions into tomato to control TMV and Tomato mosaic virus (ToMV). These genes confer resistance to nearly all strains of tobamoviruses through recognition of the viral movement protein (MP). Molecular cloning has revealed that *Tm-2* and *Tm-22* are different alleles of the same gene. They differ by only four aa, two of which are in the LRR domain. Despite this similarity, *Tm-22* has proven to be more durable than *Tm-2*. Strains of ToMV that overcome *Tm-2* or *Tm-22* have mutations in different regions of the MP. The *Tm-22* gene seems more durable because the resistance-breaking mutations have a very negative impact on virus fitness, resulting in reduced viral load in plants infected with these strains. The *Tm-22*-breaking strains cause very severe symptoms on *Tm-22* plants so that infected plants can be easily recognized and eliminated from the field or greenhouse. Other *R* genes that are very durable are *N*, *Rx1*, and *Ry*. There are no strains of Potato virus Y (PVY) that overcome *Ry* and although ObPV can overcome *N*, it is not widespread. Likewise, *Rx1*-breaking PVX strains have reduced virulence and are found only in South America. Less durable genes include *Nx* and *Nb*, where PVX strains that overcome this resistance are more widespread. Additionally, TSWV strains breaking Sw-5b resistance have been reported in several tomato-growing areas.

Not all mutations lead to a loss of fitness for the virus, for example in the case of differential recognition by the *N'* gene of tobacco. The *N'* gene confers resistance to several tobamoviruses including ToMV, but not TMV. Although *N'* has not been cloned, the Avr determinant has been shown to be the viral CP. Curiously, mutations can be introduced into the TMV CP that result in a gain of recognition by *N'*, but which appear to compromise CP function. These mutations are hypothesized to interfere with the tertiary or quaternary structure of the CP, exposing an *N'* recognition site previously masked. Differential recognition of viral Avr proteins by *R* proteins can also be seen for the products encoded by the allelic pepper genes *L1-L4*, also recognizing the CP of tobamoviruses. Certain virus strains are able to evade recognition of *L1*, and thus *L1*-mediated resistance, some overcome *L1* and *L2*, and some overcome *L1*, *L2*, and *L3*. However, the *L4* gene is very broad spectrum, controlling all known tobamoviruses.

Signaling Mechanisms

Studies with *Rx1*, *HRT*, *Sw-5b* and *N* have shown that the different domains of NB-LRR proteins undergo physical intramolecular interactions with the LRR and N-terminal domains interacting with the NB domain. These interactions appear to condition an auto-repressed state and alterations thereof are associated with activation of the protein.

In the presence of PVX CP, the interdomain interactions of *Rx1* are disrupted and the *N* protein has been shown to undergo oligomerization in the presence of p50. Both *N* and *Rx1* shuttle between the nucleus and the cytoplasm, and both depend on their nuclear localization in order to induce a defense response. Interestingly, p50 is not required in the nucleus to elicit the *N* mediated defense response, but does so even when restricted to the cytoplasm, and *Rx1* can only be activated in the cytoplasm. Similarly, the barley NB-LRR *MLA10*, and the *Arabidopsis* NB-LRRs *RRS1*, *RPS4*, and *SNC1* (suppressor of *npr1-1*), are all at least to some extent localized to the nucleus. Of these, *MLA10*, *RPS4*, and *SNC1* show a reduced immune response upon induced relocation from the nucleus to the cytoplasm. Taken together, these NB-LRRs provide evidence towards a nuclear signaling component, concurrent with one of the first steps of the immune response pathway being modification of transcription.

In vitro studies have shown that *Rx1* binds unselectively to DNA after activation through association with the PVX CP. It induces melting and bending of DNA, leading to structures resembling transcription initiation complexes. *Rx1* most likely interacts with a Golden2-like (Glk) transcription factor, as demonstrated by its binding to *Nicotiana benthamiana* Glk1 in a transient transformation assay. In *Arabidopsis*, Glk1 and Glk2 are involved in a defense response against CMV, possibly in a redundant manner. In a double mutant, induction of defense related genes is hampered. In the current *Rx1* resistance model, *Rx1* and Glk1 associate in a

complex and bind to DNA through Rx1 mediated DNA binding activity. Upon infection, the CP induces conformational changes in the Rx1-Glk1 complex, exposing the Glk1 DNA binding domain, previously blocked by the Rx1 CC domain. Glk1 binds stronger to its consensus DNA binding motifs, providing specificity to the induced transcriptional changes in the defense response. Concomitant with the role of Glk1 as an immune activating transcription factor, overexpression of Glk1 without Rx1 is sufficient to induce ER to PVX.

It is presumed that other R proteins induce a signal transduction cascade leading to disease resistance by interacting with signal adaptor molecules as well. Although these molecules have yet to be identified, a number of proteins required for NB-LRR function are known. TIR-NB-LRR proteins, including N, have a general requirement for the EDS1 (enhanced disease susceptibility 1) protein and often also require the EDS1-interacting protein PAD4 (phytoalexin deficient 4). Both of these proteins have lipase signature domains, of which no exact function is known. Given that the *N* gene is not effective above 32°C, it is interesting to note that *EDS1* expression levels are greatly reduced at higher temperatures in *Arabidopsis*. Likewise, the barley MLA NB-LRR proteins accumulate to greatly reduced levels at high temperatures. These phenomena may at least partially explain the temperature sensitivity of some *R* genes.

A number of studies have shown that during the resistance response, kinase cascades are activated, and transcription is reprogrammed substantially. Studies using virus-induced gene silencing (VIGS) have implicated several protein kinases, including MEK1, MEK2, NTF6, SIPK, WIPK, and NPK1, in *N* gene-mediated resistance. Additionally, successful *N* mediated resistance to TMV requires Beclin 1, Atg3 (autophagy related 3), Atg7, and Pi3k/Vps34 (class III phosphoinositide 3-kinase). These proteins are involved in the autophagy pathway, one of the major cellular degradation pathways in eukaryotes. Silencing these genes leads to programmed cell death beyond the infected tissue, thus for *N* mediated resistance the autophagy pathway appears involved in limiting the HR to the site of infection. Autophagy has been implicated in many plant processes, including innate immunity. Furthermore, the mammalian nod-like receptor 2 (NLRC2) activates antiviral innate immune signaling, using autophagy to regulate inflammatory responses. A requirement was also shown for the TGA and WRKY families of transcription factors as well as the individual transcription factors MYB1 (myb domain protein 1) and the TGA-interacting protein NPR1 (nonexpresser of *pr* genes 1). These proteins and protein families have also been implicated in gene-for-gene resistance to other types of pathogens. Gene-for-gene resistance may also involve targeted proteolysis since silencing the expression of certain proteins involved in regulated protein degradation, including a subunit of the COP9 (constitutive photomorphogenesis 9) signalosome, SKP1 (S phase kinase-associated protein 1 phase kinase-associated protein 1) and COI1 (coronatine insensitive 1), also compromises *N*-mediated resistance. To date, the only genes whose silencing has been shown to break Rx1-mediated resistance are *Hsp90* (*heat shock protein 90*) and *Sgt1* (*suppressor of the G2 allele of skp1*). Along with the *Sgt1* binding protein Rar1 (required for MLA12 resistance 1), these proteins are required for the function of a number of NB-LRR proteins. The *Hsp90*, *Sgt1*, and *Rar1* proteins are likely chaperoning proteins in order to allow proper protein folding.

The plant hormone ethylene plays a role in *R*-gene-mediated antiviral responses. RCY1 functions at reduced efficiency in *Arabidopsis* containing the ethylene-desensitizing mutations *ein3* and *etr1*. Salicylic acid (SA) also plays a role in *R*-gene-mediated resistance. The involvement of SA is often studied using SA biosynthetic mutants in *Arabidopsis* (such as *eds5*) or by using plants transgenically expressing the bacterial *nahG* gene, which encodes a salicylate hydroxylase that degrades SA. The *eds5* mutation and *nahG* transgene both decrease the efficiency of RCY1-mediated resistance and completely abrogate HRT-mediated resistance. When tobacco plants expressing *N* and *nahG* are infected with TMV, the resulting HR lesions are larger, and necrosis can spread beyond the infected leaf. Similarly, in *nahG* transgenic tomato the normal ER response of Tm-22 becomes a spreading HR phenotype in the inoculated leaf, although the virus does not spread systemically. The Rx1-mediated response, however, is not affected by the *nahG* transgene. SA may enhance *R* gene responses rather than directly targeting the virus, and its requirement for resistance may depend on the strength of the *R*-gene-mediated response.

In agreement with this, SA application results in reduced lesion size in the *N*-mediated response to TMV and an enhancement of HRT-mediated resistance. Cell death during the HR induces increased levels of SA. Thus, cell death may indirectly prime and/or augment *R*-gene-mediated antiviral responses. It is clear that cell death itself is not the only mechanism by which virus is eliminated as ER does not involve cell death, and in the *N*-TMV interaction, TMV can be detected outside the area of necrosis. Furthermore, in the interaction between Cauliflower mosaic virus (CaMV) and *Nicotiana spp.*, resistance is controlled by a single dominant gene. However, whether or not this resistance is accompanied by an HR is controlled by a separate gene. A clear understanding of how viruses are cleared from resistant plant cells requires further study.

Resistosome

Although multiple individual NB-LRR genes and their corresponding Avr effectors have been both identified and studied, the pathway of defense response induction in plants remains elusive. In animal systems, these mechanisms are often elucidated to a higher extent. Translating this information to plant systems could provide a valuable resource. In animal systems, one of the key factors required for resistance mediated by several *R* genes was found to be oligomerization. The highly structured complexes are referred to as either an inflammasome or apoptosome. Three well-studied examples include the human R protein apoptotic protease-activating factor 1 (APAF1), the nematode R protein cell death protein 4 (CED-4), and the human protein NLRC4. Within plants, although a similar resistance mechanism was hypothesized in 2010, only one R complex has been identified, as recent as 2019. This work involved the CC-NB-LRR protein hopz-activated resistance 1 (ZAR1), conferring resistance within *Arabidopsis* and

N. benthamiana to disease caused by the bacteria *Xanthomonas campestris*. The formation of the ZAR1 complex, termed resistosome, is essential for resistance induced by the *X. campestris* effector AvrAC.

The resistosome structurally resembles the inflammasome and the apoptosome. All three consist of a wheel-like basis, and the NB-ARC domain is similarly positioned between ZAR1, APAF1, and NLRC4 to facilitate oligomerization (Fig. 1). Furthermore, although ZAR1 oligomerization requires certain co-factors, these are not part of the interacting domains between the sub-units, similar to the co-factor cytochrome C in the Apaf1 apoptosome. Important differences include the organization of the N-terminal domains. The Apaf1 apoptosome and the NLRC4 inflammasome contain disorganized caspase recruitment domains (CARDs), in the absence of certain caspases. These caspases are interacting partners required for downstream processing of the defense signal. However, the α helices in the CC domain of the ZAR1 resistosome are highly structured. Furthermore, the number of sub-units contributing to the complex differs from five in the ZAR1 resistosome, to seven for the Apaf1 apoptosome, nine for the CED4 apoptosome, and eleven for the NLRC4 inflammasome.

Assembly of the ZAR1 resistosome requires the presence of two other proteins: resistance-related kinase 1 (RKS1) and PBS1 like protein 2 (PBL2), as well as the exchange of an ADP for ATP. Current evidence suggests ZAR1 and RKS1 form a dimer within the cytoplasm of the plant cell. Upon infection by the *X. campestris* bacteria, the AvrAc protein modifies the host protein

Fig. 1 Protein structure of the ZAR1 resistosome (A, D, G), the APAF1 apoptosome (B, E), the NLRC4 inflammasome (C, F), and the actinoporin FraC (H). Colors indicate the transition from N (blue) to C terminal (red) (A–C) or the different subunits in the complex (D–H). A–C show top views of the complexes, and D–H show side views. G shows a detail of the α helical bundle of the ZAR1 complex in D, for comparison to the α helical bundle of FraC in H.

PBL2 by the addition of a uridine monophosphate. This modified PBL2 binds to the ZAR1-RKS1 dimer, promoting the release of ADP from this complex. The subsequent binding of ATP leads to the oligomerization of this complex in a resistosome consisting of five ZAR1-RKS1-PBL2 subunits. Interestingly, the oligomerization towards the resistosome seems to differ from the activation and assembly of the human NLRP3 inflammasome, where a potassium efflux seems required in almost all cases. Although the ZAR1-RKS1 dimer is only to a very limited degree localized in the plasma membrane, resistance mediated by the resistosome complex requires its presence in the plasma membrane. To understand the translocation of the resistosome, a closer look must be taken to the rearrangements of the different ZAR1 domains during activation.

The NB-ARC domain of ZAR1 can be further divided in a NB domain, HD1 (helicase domain 1), and WHD (winged helix domain). Rearrangements within the CC domain lead to the exposure of the α 1 helix, from a position buried and contacting the LRR and WHD domain, to a position protruding from the rest of the protein. Upon oligomerization, the α 1 helices form a highly structured funnel shape. This most likely facilitates the association to the plasma membrane. Mutation of several aa in this α 1 helix, as well as adding a FLAG peptide, leads to a loss of plasma membrane association. Although these perturbations of the α 1 helix lead to loss of ZAR1 resistance, they do not affect the formation of the ZAR1 resistosome. Interestingly, this funnel shaped structure in the ZAR1 resistosome resembles that of the actinoporin fragaceatoxin C (FraC), although the proteins bear little homology. Actinoporins like FraC are pore-forming complexes found in sea anemone species, used both in defense and as a hunting strategy. FraC attaches to the plasma membrane, and oligomerizes into a complex consisting of nine subunits. This probably changes the protein conformation leading to the detachment of the N terminal α helix, and subsequent insertion of the α helices into the membrane, forming a highly structured α helical bundle. After the transition from a prepore to a pore, the membrane is no longer capable of maintaining ion balance. The presence of the nonselective hole leads to an efflux of ions and small molecules, depending on the pore size, and ultimately leads to cell injury or death. Aside from the similarities in structure between the α helical funnels of the ZAR1 resistosome and the FraC actinoporin complex, their size is also comparable, at 33 and 35 ångström, respectively. This could indicate that the ZAR1 funnel is also membrane spanning, rather than membrane inserted. Following this hypothesis, the ZAR1 resistosome could function through disturbance of the membrane integrity in a similar manner as the FraC complex, leading to localized cell death and limitation of pathogen spread. This is supported by the observation that mutating the inner surface of the ZAR1 resistosome funnel abolishes disease resistance. In animal cells, a similar route of using pore complexes to mediate a cell death response exists. For example, in humans and mice, inflammatory caspases oligomerize upon activation into an inflammasome. One such example is caspase 11, which cleaves gasdermin D (GSDMD), in a C-terminal and N-terminal part. After cleavage, GSDMD-NT oligomerizes within the cell membrane and forms pores, leading to cell death. For now, the exact resistance mechanism of ZAR1 remains unidentified, and future research will have to show whether ZAR1 functions as a pore complex as hypothesized, or through a different mechanism.

Non-NB-IRR Resistance

Although by far most identified *R* genes belong to the NB-LRR class, other classes of *R* genes should not be ignored or overlooked. In fact, breeding for resistance mediated by NB-LRR genes may prove less durable than breeding for resistance conferred by non-NB-LRR genes. This inherent disadvantage attributed to NB-LRRs is caused by the gene-for-gene relationship NB-LRRs have with pathogen Avr determinants. This puts a relatively large selection pressure on the pathogen. Any mutation in the pathogen effector leading to less recognition by the NB-LRR increases the pathogen's fitness considerably, as it is now able to infect a new host genotype. The likelihood of the frequency of this mutation rising within the population is therefore considerable, and the breeder would have to start over again by re-introducing resistance within the crop plant. Non-NB-LRR *R* genes could help alleviate this disadvantage, as often the principle of gene-for-gene resistance does not apply here. Instead, the underlying mechanism of resistance involves a more complex interplay of the pathogen and host, or the perception of more generic signals of the pathogen. Although less emphasis is placed on non-NB-LRRs *R* genes, they represent interesting sources to confer more durable (and sometimes broader) crop resistance.

One such example can be found within the major plant anti-viral RNA interference (RNAi) defense mechanism. RNAi is triggered by a highly conserved cue of viral presence in the plant cell: double stranded RNA (dsRNA). These dsRNAs are formed during viral replication, either through overlapping open reading frames (ORFs), from highly structured viral mRNAs, or as a replication intermediate of RNA viruses. During the life cycle of a healthy plant cell, dsRNA is rarely formed, rendering this form of RNA a distinctive signal to the plant cell of pathogen presence. Dicer-like (DCL) enzymes cleave these RNA duplex molecules in small fragments, typically 20–25 nt in size. One strand of these small interfering RNAs (siRNAs) is then loaded into an AGO containing RNA-induced silencing complex (RISC). Any RNA complementary to this strand is targeted for degradation, giving rise to aberrant RNA molecules, or translational arrest. During an amplification cycle, α type RNA dependent RNA polymerases (RDRs) synthesize a full-length dsRNA molecule using the single-stranded aberrant RNA molecule as a template. This full-length dsRNA is cleaved by one of the DCLs, generating a population of secondary siRNAs. These can either be used again to target complementary RNAs for silencing or spread through the plasmodesmata between plant cells, leading to immunization beyond the infected cell. Upon infection by a DNA virus, siRNAs are alternatively loaded on an RNA-induced transcriptional silencing (RITS) complex, containing a distinct AGO protein. This complex targets complementary DNA for methylation, leading to a block of transcription of viral DNA.

Table 2 Overview of cloned antiviral non-NB-LRR genes. The resistance mechanism is indicated, as well as the species in which the *R* gene is used (plant), and the viral elicitor

Resistance mechanism	<i>R</i> gene	Encoded protein	Plant	Virus	Elicitor
RNAi	Ty-1	RDR γ	Tomato	TYLCV	dsRNA
Restricted systemic movement	RTM1–5 ^a	Jacalin, HSP20, MATH, ND, ND	Arabidopsis	Potyviruses (TEV, PPV, LMV)	ND
Lectin-mediated resistance	JAX1	Jacalin	Arabidopsis	Potexviruses (PIAMV, PVX, Asparagus virus 3, White clover mosaic virus)	Replicase
Inhibition RNA replication	Tm-1	TIM-barrel-like domain	Tomato	ToMV	130K and 180K replication proteins

^aRTM mediated resistance requires the presence of all 5 genes.

Recently, *Ty-1*, one of the major dominant resistance genes against the geminivirus TYLCV (Tomato yellow leaf-curl virus) in tomato, has been cloned, and was shown to encode a member of the γ subclass of RDRs (Table 2). Previously, members of this class had not been assigned any function. The main difference between the well characterized α type and the γ type lies within the catalytic core domain, the α type containing a DLDGD motif and the γ type a DFDGD motif. *Ty-1* has been shown to confer resistance, still allowing very low levels of viral DNA replication, by enhancing the RNAi response. Specifically, it strengthens transcriptional gene silencing of viral DNA. As opposed to an NB-LRR recognizing one pathogen Avr effector, *Ty-1* potentially entails a more durable *R* gene and confers resistance to a wider range of mono-/bipartite geminiviruses, besides TYLCV. The achilles heel of *Ty-1*-mediated resistance lies in co-infecting plant viruses with the ability to interfere with antiviral RNAi using proteins called viral suppressor of RNAi (VSR).

Another interesting example can be found in the *Arabidopsis* *R* genes *Restricted tobacco etch potyvirus* (RTM) and *Sieve element lining chaperone 1* (SLI1). RTM mediated resistance requires the presence of five genes, termed RTM1–5. Together, these genes limit the spread of TEV, Plum pox potyvirus (PPV), and Lettuce mosaic virus (LMV) through the plant to systemic tissues. RTM1 encodes the lectin protein jacalin. Several members of this gene family have been shown to provide resistance to insects, fungi, and viruses. RTM2 is an unusual small heat shock protein, containing a C-terminal transmembrane domain. It is neither inducible by heat treatment, nor providing tolerance towards high temperatures. RTM3 belongs to a gene family of unknown function, whose members contain a meprin and TRAF homology (MATH) domain and a C-terminal CC domain. RTM4 and RTM5 remain uncharacterized. Although the exact resistance mechanism is unknown, resistance breaking strains rely on changes in the N-terminal region of the CP. No interaction has been shown between the CP and RTM1–3. Both RTM1 and RTM2 are shown to localize to sieve tubes, rendering it likely that the resistance acts in phloem tissues. Oligomerization of several different factors seems required, as demonstrated by both the direct interaction of RTM1 and RTM3, and the presence of several domains involved in protein-protein interactions in RTM1–3.

An alternative method of introducing resistance against viruses is by combatting vectors transmitting these viruses between plants. *SLI1* is an example of an *R* gene that could be used in such a manner. It has been recently identified and confers resistance in *Arabidopsis* against the generalist aphid *Myzus persicae* through restriction of both feeding time and phloem ingestion rate. *SLI1* limits the growth of the aphid population on the host plant, and in this manner *SLI1* could aid in limiting virus spread throughout the plant population. As opposed to RTM2, *SLI1* confers tolerance to higher temperatures. *SLI1* is lined around the entire sieve elements, including the sieve plate, and specifically around mitochondria in a peripheral strip of cytoplasm. Interestingly, RTM2 and *SLI1* are homologs belonging to the same superfamily of heat shock protein 20 (HSP20)-like chaperones.

Outlook

With the recent discovery and elucidation of the ZAR1 resistosome a new chapter has opened on the functioning of NB-LRR resistance proteins. Whereas earlier research has indicated that the actual resistance response is different from HR, findings on the ZAR1 resistosome, most likely functioning as a membrane pore, implies that cell death is an essential and final stage of the resistance response/mechanism. This (again) forces us to re-visit our views on the resistance mechanism. If the hypothesized function of ZAR1 holds true, how can HR and the so-called actual resistance response be uncoupled? Maybe on this point the resistance mechanism consists of sequential layers, with the Avr being the initial trigger to all. The first layer(s) could be pathogen-specific and the formation of a resistosome represents the final stage that is generic and always leads to cell death, irrespective of the type of pathogen. This also would explain why in most cases HR occurs concomitant with the induction of NB-LRR-gene mediated resistance. The lack of HR in several cases could then be a quantitative rather than qualitative matter, similar to the differences observed between HR, ER, and SN responses. Alternatively, this could result from mutations that prevent the *R* protein from oligomerization but not compromise the earlier, upstream steps of the resistance response.

Although speculative, the formation of different oligomers as observed with animal *R* proteins, like inflammasomes and apoptosomes, also raises the question on the existence of different resistosomes in plants. In light of this it is interesting to remark

on differences between plant NB-LRRs. For ZAR1 the CC domain is not only essential for oligomerization, but its overexpression also leads to HR. This is compromised by N-terminal fusions or -deletions at the CC domain. In contrast, for several other NB-LRR genes, not CC but overexpression of NB-ARC (e.g., Sw-5b) or NB (e.g., Rx1) triggers HR. In addition, the folding structure of the ZAR1 CC domain is different from those of stem rust resistance 33 (Sr33), Rx1 and MLA10. This indicates a possible classification of NB-LRRs into subgroups. On this point, a recent study has shown that several NB-LRRs, termed sensors, require the presence of a second NB-LRR, termed helper. These helpers can be divided in three classes: *NRC* (*NB-LRR required for cell-death*), *ADR1* (*Activated disease resistance 1*), and *NRG1* (*N required gene 1*). Interestingly, these helpers can be (partially) redundant, as in the case of NRC2, 3, and 4, while several sensors can share the same helper. Silencing all three NRCs affects, among others, resistance mediated by Sw-5b and Rx1. Subsequent challenge of NRC silenced plants carrying *Rx1* with PVX results in SN, instead of the usual ER response. This suggests NB-LRRs can be divided into at least two sub-groups, those that act without helper and those that require a helper. This could also explain why domains from different NB-LRR proteins are not all functionally equivalent in signal transduction. Building on this, a recent study revealed an N-terminal 21 aa motif, termed MADA, that is conserved among the NRC helper proteins and folds into an α helix similar to the $\alpha 1$ helix of ZAR1. Additionally, this motif is found in approximately 20% of the 988 CC-NB-LRRs tested. The MADA motif is essential for the HR response, and upon switching with the corresponding region in ZAR1 the helper NB-LRR NRC4 is still capable of conferring cell-death. Whether NB-LRRs that need a helper differ from ZAR1 in the formation of a distinct resistosome remains an intriguing question to be solved.

Despite a strong interest for dominant *R* genes, interest in non-NB-LRR genes lags behind. Their identification being more difficult and elaborate than that of NB-LRR genes has so far limited the number of antiviral non-NB-LRR genes characterized. Nevertheless, non-NB-LRR *R* genes hold a strong promise towards the future, due to their more durable nature and broader resistance spectrum.

This is an update of C. Caranta, C. Dogimont, Plant Resistance to Viruses: Natural Resistance Associated with Recessive Genes, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00735-4](https://doi.org/10.1016/B978-012374410-4.00735-4).

Nomenclature

aa	amino acid(s)	NGS	next generation sequencing
Avr	avirulence	nt	nucleotide(s)
Cas	CRISPR-associated proteins	ORF	open reading frame
CI	cylindrical inclusion	PABP	poly(A)-binding protein
CITE	cap-independent translation enhancer	PDIL5-1	protein disulfide isomerase like 5-1
cPGK2	chloroplast phosphoglycerate kinase 2	Poly(A)	polyadenylated
CRISPR	Clustered regularly interspaced short palindromic repeats	QTL	quantitative trait locus
dsRNA	double-stranded RNA	RdRp	RNA-dependent RNA polymerase
EMS	ethyl methane sulfonate	RIL	recombinant inbred line
ER	endoplasmic reticulum	SNP	single-nucleotide polymorphism
GM	genetically modified	ssRNA	single-stranded RNA
gRNA	genomic RNA	TALEN	transcription activator-like effector nuclease
HR	hypersensitive response	TILLING	targeting induced local lesions in genomes
IRES	internal ribosomal entry site	tRNA	transfer RNA
KO	knockout	UPR	unfolded protein response
mRNA	messenger RNA	Vpg	viral protein genome-linked
nCBP	novel cap-binding protein	VPS41	vacuolar protein sorting 41
		ZFN	zinc-finger nuclease

Glossary

Allele Allele is one of the distinct forms of a gene at a single locus. Show different effect on the phenotype from the other forms.

Avirulence Genetic traits for a pathogen to be impaired by genetically determined host resistance and to cause an incompatible (no disease) interaction.

Dominant allele An allele expressing its phenotypic effect even when heterozygous with a recessive allele.

Genome editing Genome editing is a technology for the modification of genomic DNA sequence (deletion, substitution, and insertion) using sequence-specific nucleases.

Paralog Paralogs are a group of genes generated by duplication events within a genome. Orthologs, which are evolved from a common ancestral gene in different species, retain evolutionally conserved functions, whereas paralogs generally evolve new functions.

Pleiotropic mutation A mutation showing multiple distinct effects.

Positional cloning Determining the location of a gene-of-interest on the chromosome without any idea of the biological function of that gene.

Quantitative trait loci Correspond to genomic regions associated with the phenotypic variation of a quantitative trait.

Recessive allele An allele whose phenotypic effect is not expressed in a heterozygote.

TILLING A reverse genetics approach that relies on the ability of a special enzyme to detect mismatches in normal and mutant DNA strands when they are annealed. It can therefore detect single point mutations of the type induced by chemicals conventionally used in mutation breeding programs.

Introduction

To defend against plant pathogenic microbes, plants deploy resistance machinery, which can be inherited genetically. Genetic resistance, also referred to as host or cultivar resistance, is determined by a specific genotype in the resistant host variety, relative to other varieties possessing distinct genotypes that confer susceptibility. Employing host resistance machinery through the conventional breeding has long been one of the most effective and sustainable ways to control diseases caused by plant pathogenic microbes including viruses.

In terms of genetics, host resistance can be classified as monogenic, digenic, or polygenic ones, governed by one, two, or several genes, respectively. Most monogenic and digenic types of resistance are characterized by qualitative resistance phenotypes, such as the complete absence of pathogen proliferation. In contrast, most polygenic resistance is phenotypically quantitative, underlined by several resistance genes generally called quantitative trait loci (QTLs). QTL mapping is the main technique used to identify genetic markers statistically linked to the resistance phenotype, in which the recombinant inbred lines (RILs) derived from the crosses between parents with different resistance traits are used to collect the phenotypic data. In practice, the development of genetic markers tightly linked to resistance traits has been quite valuable for the conventional breeding of resistant plant varieties.

Host resistance can be inherited in a dominant or recessive manner. Almost half of the host resistance against plant viruses that have been characterized in natural plant ecotypes are inherited recessively. This high ratio of recessive inheritance is specific to plant viruses and has not been observed for other plant pathogens, such as oomycetes, fungi, and bacteria: this feature is closely related to the distinct infection cycles of plant viruses, as will be discussed later.

The degree of recessively inherited resistance ranges from partial to complete inhibition of pathogen invasion. Some plants with partial resistance show “tolerance,” in which symptom attenuation and/or no crop yield loss is observed, even under complete systemic infection by the pathogens. More phenotypic variation is observed for recessive resistance, than for dominant resistance, which mainly involves pathogen confinement at the initial infection site and is frequently associated with localized cell death, also known as hypersensitive response (HR). Recessive resistance can interrupt viral infection at any stage of the infection cycle, including during viral protein translation, viral genome replication, and cell-to-cell and systemic movement.

Resistance breakdown by the emergence of a virus strain with genome mutations frequently accompanies recessive resistance in agricultural fields. Comparative genetic analysis using resistance-breaking viral strains can be used to identify the viral avirulence (Avr) factors that determine recessive resistance. Functional analysis of the interaction between the viral Avr factor and the plant resistance gene product promotes our understanding of the molecular dialog between viruses and their host plants, and contributes to the development of new breeding strategies based on natural recessive resistance to avoid resistance breaking.

In this article, we demonstrate the phenotypic and molecular characteristics of natural virus recessive resistance in plants, and describe recent advances in this field.

Overview of Naturally Occurring Recessive Resistance

Recessive resistance is a highly relevant trait for virus-resistant crop breeding. The ratio of recessive to dominant resistance to plant viruses is much higher than those of resistance to pathogens from other kingdoms, including oomycetes, fungi, and bacteria. Examples of recessive resistance found in nature, drawn from a survey of the literature, are shown in [Table 1](#). Recessive resistance to viruses has been observed in dicots and monocots. It has been studied most intensively in the dicots families Fabaceae, Cucurbitaceae, and Solanaceae, and in the monocots barley and rice. Recessive resistance is rarely found in polyploid plants, likely due to the presence of dominant gene copies with redundant function. However, one allopolyploid plant, *Brassica juncea* (mustard), encodes recessive resistance gene *retr03*, which has been found at a higher than expected ratio in 7 resistant landraces among 35 tested.

Inherently recessive resistance has been characterized for viruses of diverse taxa, with various types of RNA- or DNA-based genome structure. Many of these viruses belong to the genus *Potyvirus*. Potyviruses are single-stranded RNA viruses that account for about 70% of the recessive resistance in a wide range of plant species, together with other related viruses encoding the viral protein genome-linked (VPg) protein, which binds to the 5′ end of their genomic RNA as a cap analog. *Potyvirus* is the largest genus of phytopathogenic viruses; it contains many virus species that cause severe crop yield losses worldwide. The frequency of recessive resistance varies among virus families and genera: it is almost 50% in the genus *Potyvirus*, but rare in other virus genera, such as *Tobamovirus*. This inconsistency is likely to relate to virus infection strategies and selection pressure due to viral infection in natural plant habitats. Thus, the frequency of recessive resistance for a specific plant–virus interaction may be determined by a trade-off between the fitness costs of recessive mutations of resistance genes and the costs of viral infection to healthy plant growth.

Several resistance loci control distinct strains of single virus species, or two or more distinct viral species. In barley (*Hordeum vulgare*), two distinct alleles, *rym4*, and *rym5*, at a single recessive locus confer resistance to several bymoviruses, including Barley mild mosaic virus (BaMMV), Barley yellow mosaic virus (BaYMV), and Barley yellow mosaic virus-2 (BaYMV-2). Alleles at the *pvr2* locus in pepper (*Capsicum* spp.) are responsible for resistance to several potyviruses, including Potato virus Y (PVY), Tobacco etch virus (TEV), and Pepper mottle virus (PepMoV). Another example is pea (*Pisum sativum*) with two well-documented recessive resistance loci against several potyviruses. At the first locus are *bcm* against Bean common mosaic virus (BCMV), *cyr1* against Clover yellow vein virus (CIYVV), *mo* against Bean yellow mosaic virus (BYMV) and Watermelon mosaic virus (WMV), *sbm-2* against Pea seed-borne mosaic virus (PSbMV), and *pmv* against Pea mosaic virus (PMV). At the second locus are *sbm-1*, *sbm-3*, and *sbm-4*, conferring resistance to three PSbMV strains, *cyr2* against CIYVV, *wlv* against BYMV, and *mo1*¹ and *mo1*² against Lettuce mosaic virus (LMV). With recent advances in the molecular understanding of natural recessive resistance, discussed below, the broad resistance spectrum of these loci has been attributed to the action of a single gene with a pleiotropic effect.

Although recessive resistance is usually governed by a single gene, it is controlled by two distinct loci in several plant–virus pairs. In common bean (*Phaseolus vulgaris*), resistance against BCMV pathotypes requires two complementary genes at the *bc-u* locus and at one of the three strain-specific loci (*bc-1*, *bc-2*, and *bc-3*). Interestingly, in pepper, only the *pvr2* locus controls resistance against potyviruses including PVY, whereas the *pvr6* and *pvr2* loci are required for recessive resistance to another

Table 1 Virus recessive resistance found in hosts

^aAbbreviations: CR, complete resistance; chr, chromosomes; PR, partial resistance; ≠, independent; SL, symptomless; Cell R, cellular resistance (resistance at a single cell level); To, tolerance; SI, systemic infection; Mvt, movement; Red, reduced; Acc, accumulation; Inoc, inoculated; HR, hypersensitive response; S, symptoms; R, resistance.

potyvirus, Pepper vein mottle virus (PVMV). These phenomena imply that the pyramiding of independent resistance loci in a single cultivar, if possible, would broaden the spectrum of recessive resistance.

Among a number of studies performing the genetic analysis on resistances governed by QTLs, some of them have been proved to be recessive. For example, quantitative recessive resistance in a melon cultivar to Cucumber mosaic virus (CMV; *Cucumovirus*, family *Bromoviridae*) is conferred by polygenes including the major QTL *cmv1*. In melon, the major QTL *wmv*¹⁵⁵¹, together with three minor QTLs on different chromosomes, regulates recessive resistance against WMV. The major QTL *qMrdd1*, which confers recessive resistance against maize rough dwarf disease caused by a group of viruses in the genus *Fijivirus*, family *Reoviridae*, has also been mapped in maize. The major QTL *rymv*-QTL1 in rice modulates quantitative recessive resistance to Rice yellow mottle virus (RYMV; *Sobemovirus*, family *Solemoviridae*). Interestingly, *rymv*-QTL1 was mapped to the same locus as the monogenic recessive resistance gene *rymv2*, indicating that the same gene can be involved in quantitative and qualitative resistance.

Cloned Recessive Resistance Genes

Plant viruses rely heavily on a number of host factors, also referred to as susceptibility factors, in host cells to replicate their genomes and spread into healthy tissues. In host cells, viruses must simultaneously deal with multiple defense responses by plant innate immune systems. Due to such inherent nature of virus infection strategies in host cells, recessive resistance is hypothesized to be genetically explained by loss-of-function (null) or point mutations of a gene encoding a host factor involved in viral infection, and of a negative regulator of defense responses. Both parts of this hypothesis appear to be supported by recent developments in the cloning and the characterization of recessive resistance genes found in natural plant germplasm (Table 2).

Eukaryotic translation initiation factor 4E (eIF4E)-mediated recessive resistance has been observed in a wide range of plant species, including dicots and monocots. The possible involvement of eIF4E in plant viral infection was first documented by the isolation of an isoform of eIF4E (eIFiso4E) as an interactor of the VPg protein of Turnip mosaic virus (TuMV) in a yeast two-hybrid assay. eIF4E-mediated resistance has been discovered in various crop species via the candidate gene approach. Additionally, there are also distinct classes of the recessive resistance genes in terms of their intrinsic functions in host plants, including both dicots and monocots, against a wide range of viruses. Elucidation of the characteristics and mechanisms of the natural recessive resistance would create a foundation for the development of the new plant breeding strategies for virus resistance. Recent findings imply the existence of an unexpected regulatory mechanism for natural recessive resistance, rather than a simple working hypothesis

explained by null mutation of a single susceptibility factor. A deeper understanding of recessive resistance in natural germplasm will be valuable for durable resistance applications in crop species.

Characteristics of eIF4E-Mediated Recessive Resistance

The first molecular cloning of a naturally occurring recessive resistance gene revealed that *eIF4E* gene is responsible for *pvr2*-mediated resistance against PVY and TEV in pepper (*Capsicum annuum*). Although a number of susceptibility factors has been identified from naturally resistant accessions and artificially induced mutants, and as interactors of viral proteins in various plant species, the most-studied naturally recessive resistance genes remain *eIF4E*, its interacting partner *eIF4G*, and their isoforms (hereafter *eIF4Es*).

The protein eIF4E is commonly involved in canonical translation of mRNA in eukaryotic cells. eIF4E physically interacts with eIF4G scaffold proteins to form the eIF4F translation initiation binary complex. This complex initially binds to the m⁷G cap structure at the 5' end of mRNA through the eIF4E subunit. Subsequently, eIF4G recruits several other initiation factors, such as poly(A)-binding protein (PABP); eIF4A, a helicase for the unwinding of RNA secondary structures; and eIF3, a multi-subunit complex that binds to the 40S ribosomal subunit (Fig. 1). The eIF4F complex induces the close interaction of both termini within the mRNA molecules in a process termed circularization, which promotes efficient translation.

Fig. 1 The eukaryotic translation initiation complex. eIF, eukaryotic initiation factor; PABP, poly(A)-binding protein; 40S, 40S ribosomal subunit. Reproduced from Robaglia, C., Caranta, C., 2006. Translation initiation factors: A weak link in plant RNA virus infection. *Trends in Plant Science* 11(1), 40–45.

Plants possess two isoforms of eIF4E: eIFiso4E, and novel cap-binding protein (nCBP). eIF4E and eIFiso4E form the distinct protein complexes eIF4F and eIFiso4F with eIF4G and eIFiso4G, respectively. Although these complexes can have partially redundant functions in the protein translation machinery, each complex selectively recruits specific mRNA species for translation. Genes encoding the components of the eIF4F complexes constitute a small gene families in plants. For example, in the model plant *Arabidopsis*, three genes (*eIF4E1*, *eIF4E2*, and *eIF4E3*) belongs to the eIF4E subfamily, one gene belongs to eIFiso4E; one gene belongs to eIF4G; two genes (*eIFiso4G1* and *eIFiso4G2*) belongs to the eIFiso4G subfamily. Thus, the paralogous genes in each subfamily showing high degrees of sequence similarity are predicted to be functionally redundant in the translation machinery.

The protein eIF4Es may have biological functions other than translation initiation. eIF4E and/or eIFiso4E have been deduced to be involved in the nuclear export of a subset of mRNA molecules. The eIFiso4F complex may regulate microtubule dynamics through the physical interaction of eIFiso4G with microtubules. In addition, each component of the two eIF4F complexes had been demonstrated to be a susceptibility factor for some plant viruses, especially those encoding VPg. In contrast, although nCBP has a sequence motif related to eIF4E and less cap-binding activity than eIF4E and eIFiso4E, its intrinsic function in the plant translation machinery and interacting partners remain unknown. However, nCBP has been recently reported to be a susceptibility factor for several potexviruses (family *Alphaflexiviridae*) in *Arabidopsis*, and of Cassava brown streak virus (CBSV) and Ugandan cassava brown streak virus (UCBSV; genus *Ipomovirus*, family *Potyviridae*) in cassava (*Manihot esculenta*).

As mentioned above, more than half of recessively inherited resistance alleles are associated with potyviruses. Similarly, the majority of viruses influenced by eIF4E-mediated resistance are potyviruses. This dominance of potyviruses may be consistent with the relevance of this large virus group in agricultural production. Given the essential role of eIF4Es in translation and the lack of their own translational machinery for plant viruses, all plant viruses very likely utilize the eIF4Es for the translation of viral factors. Nevertheless, a limited range of virus species is impaired by mutation of one of these translation initiation factors, suggesting that some potyviruses have a fitness advantage in their infection cycles characterized by specific interaction with one of the eIF4Es possessing redundant functions. In contrast, as mentioned above, resistance to PVMV in pepper requires both *pvr6* and *pvr2-eIF4E*. *pvr6* encodes a loss-of-function variant of the *eIFiso4E* gene, suggesting that PVMV can recruit both eIF4E and eIFiso4E to establish infection.

Except for the *pvr6* resistance gene in pepper, almost all natural recessive resistance alleles related to *eIF4Es* possess only several point mutations in their coding regions, which do not interfere with the intrinsic function of eIF4E variants in plant cells. To date, several surveys of natural variation in *eIF4E* alleles in various crop cultivars indicated that the nonsynonymous substitutions correlated with the resistance phenotype are predominantly found at the non-conserved aa residues near the cap-binding pocket; these substitutions occurs in two adjacent regions on the surface of the predicted three-dimensional eIF4E structure. Functional resistance alleles with subtle aa substitutions are also known in other viruses affected by eIF4E-mediated recessive resistance, such as bymoviruses, RYMV, and Melon necrotic spot virus (MNSV). In pepper, lettuce, and pea, several allelic series show distinct resistance specificity against different virus species and pathotypes. These series represent multiple combinations of point mutations at a small number of residues, enabling multiple distinct resistance specificities.

Another common feature of eIF4E-mediated resistance is that VPg, a viral protein covalently attached to the 5' end of viral RNA, has been annotated as an Avr factor of bymoviruses and sobemoviruses, and potyviruses. A few other viral factors, including the P1 cistron of CLYVV in pea and the cylindrical inclusion (CI) protein of LMV in lettuce, have been characterized as Avr proteins. Remarkably, the Avr determinant of MNSV for *nsv-eIF4E*-mediated recessive resistance in melon can be mapped to 3' cap-independent translation enhancer (3'-CITE) at 3' untranslated region of the viral genome, but not to viral proteins. Interestingly, the incompatibility of the MNSV 3'-CITE with eIF4E may also explain non-host resistance against MNSV in *Nicotiana benthamiana*.

The roles of eIF4Es in plant–virus interactions have long been studied using *Arabidopsis*. Similarly, *Arabidopsis* mutants of *eIF4Es* introduced by ethyl methane sulfonate (EMS) treatment or transposon knockout (KO) show phenotypes characterized by loss of

susceptibility to several plant RNA viruses, including potyviruses, CMV, and Turnip crinkle virus (TCV; *Carmovirus*, family *Tombusviridae*). Such phenotypes are genetically equivalent to natural recessive resistance found among crop cultivars. However, no natural *Arabidopsis* ecotype deploying eIF4Es-mediated recessive resistance has been identified to date, implying that *Arabidopsis* has a greater fitness advantage during probable interactions with viruses relying on eIF4Es than conferred by recessive resistance mutation in *eIF4Es*. Functional specificities to eIF4Es of particular viral strains appear to be distinct between *Arabidopsis* and crop species. For instance, whereas TEV and LMV rely on eIFiso4E to infect *Arabidopsis*, they rely on eIF4E to infect pepper, tomato, and lettuce. These results highlight the significance of the basic research to reveal specific interactions among eIF4Es and viruses in crop species and model plants for the development of recessive resistance cultivars.

Molecular Mechanisms of eIF4E-Mediated Recessive Resistance

Due to the early cloning of *eIF4Es* as recessive resistance genes, which have the most dominance among cloned resistance genes, the molecular mechanism of recessive resistance governed by *eIF4Es* has been the most intensively studied so far. The two main topics of this research area have been the molecular characterization of viral Avr factors, mainly the potyvirus VPg protein, and the functional analysis of natural allelic variation in *eIF4Es* in crops and wild relatives. These studies have provided profound insight into the principles and diversity of molecular mechanisms of eIF4E-mediated recessive resistance.

In most cases, it is well known that *eIF4E* resistance alleles fails to physically interact with the potyvirus VPg protein (Fig. 2). Given that point mutations in *eIF4E* resistance alleles are mainly found near the cap-binding pocket, eIF4E-mediated recessive resistance against potyviruses is plausibly due to the disruption of eIF4E–VPg interaction. Point mutations of eIF4Es may abolish the recruitment by VPg, instead of the 5' cap structure of intrinsic mRNA for translation of the potyvirus genome. This hypothesis is consistent with the finding that eIF4G, as well as eIF4E, is a susceptibility factor for CIYVV in *Arabidopsis*, suggesting that the eIF4F complex is involved in potyvirus infection. However, a few inconsistencies were found in the correlation of eIF4E–VPg interactions with resistance phenotypes, implying the existence of another distinct mechanism for resistance against at least a few potyviruses that is functionally independent of such interaction. Alternatively, it is possible the methods used to detect eIF4E–VPg interactions, such as the yeast two-hybrid assay, may not perfectly represent these biological interactions in host cells.

Intriguingly, each plant–virus pair shows diversity of infection steps and the extent to which viral infection is impaired in eIF4E-mediated resistance against potyviruses (Table 1). Different levels of recessive resistance against a virus are frequently observed on distinct alleles at a single locus in a host. This may also support the hypothesized diversity of potyvirus infection strategies, some of which are independent of eIF4E–VPg interaction. Alternatively, eIF4E may be involved in multiple steps of the potyvirus infection cycle. Thus, distinct *eIF4E* alleles may differentially change the eIF4E function at each step in a qualitative or quantitative manner, generating diversity within the resistance phenotype.

The translation of viral proteins from genomic RNAs of PVY and TuMV had been proposed to depend on the internal ribosomal entry site (IRES), suggesting an alternative hypothesis that the eIF4E–VPg interaction does not directly control genomic RNA translation. Rather, VPg may cause host translation shutoff via interaction with eIF4E. Such activity promotes the release of translation initiation factors and/or ribosomes from host mRNA translation, thereby directing eIF4E to translate viral proteins. Since replication is tightly linked to translation during the plant viral infection cycle, eIF4E–VPg interaction had also been proposed to control replication, rather than translation. Indeed, the VPg region of the 6K2-VPg-Pro polyprotein has been demonstrated to be recruited into the viral replication complex (VRC) in TuMV-infected cells.

A few exceptions to the role of VPg as an Avr determinant of recessive resistance have been found. For example, the breaking of *mol1*-mediated resistance is attributed to a single aa mutation of the LMV CI, which is involved in potyviral replication and systemic movement. Recessive resistance mediated by *cyl2* is also overcome by an aa substitution of the CIYVV P1 cistron. In the sobemovirus RYMV, virulent VPg protein has been shown to interact with eIFiso4G, but not with eIF4E. These results indicate

Fig. 2 Predicted three-dimensional structural model of the PVY VPg (green) and eIF4E (blue) complex. W56 in eIF4E protein indicates the tryptophan residue that interacts with the cap structure. Nt, N-terminus; Ct, C-terminus. Reproduced from de Oliveira, L.C., Volpon, L., Rahardjo, A.K., *et al.*, 2019. Structural studies of the eIF4E-VPg complex reveal a direct competition for capped RNA: Implications for translation. *Proceedings of National Academy of Science of the United States of America* 116, 24056–24065.

qualitative differentiation in the mechanism of resistance mediated by *eIF4E*, even between closely related viruses. VPg may not be the sole interactor with *eIF4Es*; other viral factors together with VPg, including the polyprotein intermediates containing the VPg domain, may also play essential roles in this interaction.

The *eIF4Es*-mediated recessive resistance has also been found to be functional against viruses with distinct genomic structures, such as the lack of VPg, clearly suggesting a resistance mechanism distinct from the one mediated by *eIF4Es* against VPg-containing viruses. As mentioned above, *nsu-eIF4E*-mediated resistance against MNSV is attributed to the 3'-CITE sequence, which is an Avr factor. A resistance-breaking strain of MNSV had been shown to gain the ability to interact with *eIF4E* from resistant melon. Although direct evidence for the molecular resistance mechanism remains lacking, *eIF4E* may facilitate circularization of MNSV genomic RNAs via interaction with 3'-CITE.

Large-scale surveys of natural polymorphism of *eIF4E* alleles in several crops and their wild relatives have been conducted to explore the genetic variation and evolutionary patterns of *eIF4E* recessive resistance loci. KO mutations of *eIF4E* has not been found among natural accessions in these surveys. Although artificial development of an *eIF4E* KO mutant in *Arabidopsis* is possible, this may be due to the moderate greenhouse conditions normally used in *Arabidopsis* research. In a survey using the wild pepper chiltepin (*Capsicum annuum* var. *glabriusculum*), which is undergoing early domestication, *eIF4E* resistance alleles were frequently found in cultivated chiltepin populations. The same trend has also been reported for bymovirus resistance in barley, where possible *eIF4E* resistance alleles are predominantly encoded in domesticated barley accessions. In contrast, a survey of melon wild relatives successfully found several natural alleles of *eIF4E* genes, but no correlation of these alleles with the resistance phenotype. These findings indicate that human management of plant populations exerts profoundly strong selection pressures on the diversity and evolution of recessive resistance genes.

Each potyvirus species has evolved to specifically recruit one *eIF4E* for viral infection, despite functional overlap among *eIF4Es* in the host translational machinery. Therefore, if possible, simultaneous KO of *eIF4Es* is desirable for the engineering of broad-spectrum resistance against viruses. However, several lines of evidence suggest that double mutation of *eIF4Es* is harmful to plant development. In *Arabidopsis*, the *eif4e/eifiso4e* double-KO mutant shows a lethal phenotype; in tomato, functional repression of two *eIF4E* paralogues, *eIF4E1* and *eIF4E2*, by RNA silencing induces severe dwarf phenotypes.

Given the functional relevance of *eIF4Es* in host translation, it is plausible that simultaneous mutation of two *eIF4Es* cause severe defects in plant growth. Despite these results, recent studies have suggested that natural resistance alleles would solve the problem attributed to the intrinsic function of *eIF4Es* to create a broad resistance spectrum. Tomato *pot-1-eIF4E1*-mediated resistance, which is attributed to a small number of *eIF4E1* aa mutations, impairs infection by PVY and TEV strains. In contrast, KO mutation of *eIF4E1* in tomato yields a much narrower spectrum of resistance. Furthermore, the broad spectrum of resistance found in natural alleles can be reconstituted by artificially combining KO mutations of *eIF4E1* and *eIF4E2* in tomato with severe growth defects, indicating that *eIF4E2* also has the capacity to participate in potyvirus infection, and that *pot-1-eIF4E* negatively regulates *eIF4E2* in the potyvirus infection cycle without no detriment to plant growth. Consistently, overexpression of the *eIF4E1* resistance allele in tomato provides dominant resistance to potyviruses, even in the presence of the intrinsic *eIF4E1* susceptible allele. These results suggest that *eIF4E1* resistance alleles negatively control *eIF4E2* with redundant function to obtain a broad spectrum of resistance. This may coincide with the fact almost all *eIF4E* resistance alleles identified to date sustain only several point mutations, but not null mutations.

New Recessive Resistance Genes Found in Natural Diversity

In the past decade, several distinct classes of recessive resistance genes other than *eIF4Es* have been discovered from a wide range of plant species. A few of these genes likely have functions similar to those of *eIF4Es* in recessive resistance, due to their known intrinsic functions in the translation machinery. Others appear to have a distinct recessive resistance mechanism, involving a negative defense regulator in recessive resistance. These newly identified recessive resistance genes show different specificities of resistance to plant viruses than those mediated by *eIF4Es*. Given candidate gene approaches have helped identify *eIF4E* resistance alleles in various crops, recent progress on the new recessive resistance genes will further promote to identify the resistance genes responsible for other plant-virus interactions, and will increase the potential of recessive resistance (in terms of the resistance spectrum and the gene repertoire) in the development of resistant cultivars in a wide range of crops.

In barley, although the recessive resistance genes *rym4/rym5*, which are alleles of *eIF4E*, are frequently overcome by BaMMV and BaYMV resistance-breaking isolates, cultivars with the *rym11* locus are highly resistant against both virus isolates. The *rym11* locus has been demonstrated to encode an allele of *protein disulfide isomerase like 5-1* (*PDIL5-1*), a distinct type of recessive resistance gene. A natural polymorphism survey of *PDIL5-1* genes suggested that most *rym11* resistance alleles are likely the results of frequent interactions with highly divergent forms of BaMMV and BaYMV in eastern Asia. *PDIL5-1* is an endoplasmic reticulum (ER)-localized chaperone in plants and animals; it plays an essential role in the unfolded protein response (UPR), a cellular machinery that alleviates unfolded protein overload in ER. Although the mechanism of *rym11-PDIL5-1*-mediated recessive resistance remains unknown, downregulation of other UPR components commonly impairs efficient viral infection in several plant-virus pathosystems, implying that they are promising targets for recessive resistance to a wide range of viruses.

Distinct classes of recessive resistance genes against potyviruses have also been cloned. Single-point mutation of eukaryotic translation initiation factor 2B β (*eIF2B β*) is responsible for the *retr03* resistance locus against TuMV in allopolyploid mustard. *eIF2B β* is a subunit of the *eIF2B* complex, which mediates guanine nucleotide exchange in *eIF2* in the later step of *eIF4E* in translation initiation. The role of *eIF2B β* in TuMV infection, although still unknown, may be as a host factor because of the

intrinsic function related to eIF4E in translation initiation. Similarly, a susceptibility factor EXA1 for potexviruses, identified from loss-of-susceptibility mutant of *Arabidopsis*, contains a putative eIF4E-binding motif. These findings imply that the factors functionally related to eIF4E are promising targets for recessive resistance. *eIF2B β* recessive resistance alleles are frequently found in several mustard cultivars, albeit those with allopolyploid genomes, suggesting the relevance of this gene in mustard–TuMV interaction. Another distinct type of recessive potyvirus resistance gene is nuclear-encoded *chloroplast phosphoglycerate kinase 2* (*cPGK2*), validated in *Arabidopsis* ecotypes, independently designated WMV resistance loci *rw1*, and *rpv1* against Plum pox virus (PPV). *cPGK2* gene homologs are found in a diverse range of plants, including dicots and monocots. Consistently, knockdown of *cPGK* genes in *N. benthamiana* compromises efficient accumulation of Bamboo mosaic virus (BaMV; *Potexvirus*, family *Alphaflexiviridae*). In addition, *cPGK2* is predicted to recruit BaMV genomic RNA to chloroplasts for BaMV replication. Although the exact molecular mechanism of *cPGK2*-mediated resistance in *Arabidopsis* ecotypes remains uncertain, *cPGK2* may be a general susceptibility factor for at least a subset of potyviruses and other distantly related viruses.

A mutation in *vacuolar protein sorting 41* (*VPS41*) gene has been demonstrated to be involved in resistance against CMV, mediated by the recessive allele *cmv1* in melon. *VPS41* plays a role in membranous vesicle trafficking from the late Golgi to the vacuole in eukaryotic cells. Intriguingly, in cucumber, the gene encoding another vesicle trafficking component, *VPS4*, has been proposed as a strong candidate of the recessive resistance locus *zym* against Zucchini yellow mosaic virus (ZYMV; *Potyvirus*, family *Potyviridae*). Although evidence for a specific molecular mechanism for *cmv1-VPS41*-mediated resistance is insufficient, several viruses appear to commonly recruit components of the vesicle trafficking machinery for efficient infection.

In an African rice (*Oryza glaberrima*) accession that is resistant against Rice yellow mottle virus (RYMV; *Sobemovirus*, family *Solemoviridae*), the *rymv2* resistance gene encodes an allele of the rice homolog of the *Arabidopsis* *CPR5* gene, whose dominant form plays a negative role in the plant defense response. Seven other African rice accessions also encode *rymv2* resistance alleles. Because of the *CPR5* function in *Arabidopsis* defense responses, *rymv2-CPR5*-mediated resistance is highly likely the first example of the activation of defense responses by recessive mutation of a negative defense regulator gene.

Remarkably, the recessive resistance locus *ty-5* in tomato has also been identified to confer resistance to a plant DNA virus, Tomato yellow leaf curl virus (TYLCV; *Begomovirus*, family *Geminiviridae*). The *ty-5* locus has been reported to encode an allele of *Pelota*, whose protein product is implicated in the recycling phase of translation, the latest step of protein biosynthesis. Although the resistance mechanism mediated by *Pelota* remains unclear, this result reinforces the relevance of the host translational machinery in recessive resistance despite significant differences in infection strategies among DNA and RNA viruses.

Collectively, the identification of these distinct classes of recessive resistance genes will broaden the potential for recessive resistance application to the plant–virus pathosystem, for which this type of resistance has never been described.

Toward the Application of Recessive Resistance in Agriculture

In the last ten years, due to the increase in the acquisition of genomic information and the development of techniques for the analysis of gene functions, greater numbers of studies have identified several classes of recessive resistance genes and provided mechanistic insight on recessive resistance. Loss of susceptibility to viral infection is genetically equivalent to natural recessive resistance. Therefore, random mutagenesis using crops and model plants would extend the potential to identify unknown susceptibility factors and find new ways to utilize host factors beyond the genetic variations found in naturally occurring cultivars. Model plants further facilitate the isolation of loss-of-susceptibility mutants and subsequent identification of responsible genes, due to the availability of high-quality whole-genome sequence, simple genetic approaches, and many other analytical tools. However, it should be noted that the generation of polyploid plant mutants with desired phenotypes by random mutagenesis is often difficult due to the presence of redundant genes.

Conventional breeding techniques based on crossbreeding and molecular marker selection has long been used to introduce the recessive resistance phenotypes from one cultivar to another elite cultivar. This method has contributed to the alleviation of crop yield losses caused by devastating viruses. However, the stable introduction of resistant traits to establish resistant cultivars through conventional techniques or by the targeting of a specific gene using random mutagenesis and screening are substantially technically challenging and time consuming.

Targeting induced local lesions in genomes (TILLING) is a technology applied to rapidly identify a mutant plant with genetic modification in a target gene by combining random mutagenesis by ethyl methanesulfonate (EMS) and single-nucleotide polymorphism (SNP) detection in a specific gene. TILLING has been successfully applied to establish a null allele of *eIF4E* gene in tomato showing loss of susceptibility to potyviruses. As discussed above, the range of resistance conferred by the null *eIF4E* allele is narrower than that of the natural functional allele *pot1*. Thus, at least when *eIF4E* is the gene of interest, functional resistance alleles are preferable to a null allele for obtaining a broad spectrum of resistance. EcoTILLING is a derivative of TILLING that is used to isolate the genetic variation of a target gene from that in natural cultivars. Using the EcoTILLING approach, several natural allelic variations of *eIF4E* gene have been found in wild relatives of melon; however, they do not correlate with potyvirus resistance phenotypes. Considering the results of other surveys of natural allelic polymorphism, EcoTILLING for natural resistance alleles may be performed more effectively with collections of crop cultivars, rather than their wild relatives.

Significant technological and conceptual progress is currently being made in further promoting the application of recessive resistance and loss of susceptibility for resistant crop breeding. Sometimes, the elimination of an undesired trait that is tightly linked to the resistance phenotype using conventional breeding techniques is difficult. However, the recent emergence of

next-generation sequencing (NGS) technology and genome editing could pave the way for the rapid introduction of recessive resistance phenotypes to crop cultivars as intended.

NGS technology promotes access to the whole-genome sequences of all organisms. Genomics-based crop breeding combined with NGS is expected to enable the rapid establishment of new crop cultivars with desirable traits. NGS technology, which have rarely been applied to antiviral crop breeding using natural variants, would be quite useful for the identification of loci including major resistant QTLs (e.g., QTL-seq) in naturally resistant variants, as well as for crop breeding, to introduce resistant loci into elite cultivars.

Genome editing technology is based on sequence-specific nucleases, including zinc-finger nuclease (ZFN), transcription activator-like effector nuclease (TALEN), and clustered regularly interspaced short palindromic repeat (CRISPR)-associated protein 9 (Cas9) in the system referred to as CRISPR/Cas. These technologies, which have emerged during the last two decades to enable mutagenesis and insertion at specific genomic sites in eukaryotic genomes, are now widely used in diverse crop species, as well as model plants. Targeted mutagenesis, made possible by genome editing, can overcome potential problems caused by existing technologies, such as the time-consuming aspect of random mutagenesis and potential tight linkage of undesired traits in crossbreeding.

One advantage of genome editing for crop breeding is that the original transgenes can be removed after editing via segregation. This feature permits the removal of bottlenecks for social acceptance of traditional genetically modified (GM) crops. The CRISPR/Cas9 system was applied to modify *eIF4E* genes in *Arabidopsis*, cucumber, and rice. As expected, the resulting mutant plants, which were free of transgenes, exhibited recessive resistance to potyviruses and waikaviruses. Multiple gene editing has been demonstrated in model plants *Arabidopsis* and rice, and is thus possible in polyploid plants. Genome editing technologies can be also applied to develop loss-of-susceptibility mutants by modifying host factors identified through basic research on plant-virus interactions. In this sense, genes encoding host factors with loss-of-susceptibility mutations in *Arabidopsis* and other plant species can be regarded as potential recessive resistance genes. As a proof of concept, nCBP, known as an *eIF4E* isoform, was isolated in cassava as an interactor with VPg proteins of two ipomoviruses, CBSV and UCBSV. CRISPR-Cas9-mediated editing of two cassava *nCBP* genes successfully generated a resistant phenotype. Considering that nCBP is a susceptibility factor for potexviruses in *Arabidopsis*, *nCBP* gene is a promising target of genome editing to obtain recessive resistance with distinct spectrum from *eIF4E*-mediated resistance. Furthermore, genome editing technologies are evidently compatible with the application of current knowledge of recessive resistance in antiviral resistance breeding of various crop species, including polyploids. Derived from the original CRISPR/Cas9 system, precise base editing has been accomplished using a new technology termed Target-AID, in which a nuclease-deficient Cas9 mutant is fused with activation-induced deaminase (AID), which catalyzes C to T mutations. This technology has been utilized to confirm that base editing of the *eIF4E* gene mimicking the pea *sbm1* allele achieved recessive resistance against CIYVV in *Arabidopsis*, where no natural *eIF4E* resistance allele has been found.

Conventionally, recessive resistance traits must be introduced into new crop species from closely related species that exhibit recessive resistance and can be crossbred. Since some crop species lack recessive resistance traits, random mutagenesis has been the only method for establishment of a resistant mutant in which a susceptibility gene is knocked out. However, in tomato, the *eIF4E1* KO mutant shows a much narrower potyvirus resistance spectrum than does the natural *pot1-eIF4E1* resistance allele. Considering this finding together with other results, researchers have hypothesized that the *pot1* resistance allele, which maintains function in translation, negatively regulates *eIF4E2* with redundant function in viral infections. Based on this insight, the researchers tested whether introgression of synthetic *eIF4E* (*eIF4E^R*) alleles, rationally-designed from the pea *sbm1* gene in trans-species manner, produces a broad resistance spectrum in the background of double KO of *eIF4E/eIFiso4E* (*eif4e^{KO}/eifiso4e^{KO}*) in *Arabidopsis*. The *Arabidopsis* genotype *eIF4E^R/eif4e^{KO}/eifiso4e^{KO}* confers no growth defect and shows a broad spectrum of resistance to several potyviruses, and more significantly, to WMV and one strain of Beet western yellows virus (BWYV; genus *Polytivirus*, family *Luteoviridae*), to both of which no recessive resistance has been documented in either KO mutant, *eif4e^{KO}* and *eifiso4e^{KO}*, in *Arabidopsis*. These results suggest the new crop breeding concept of developing a synthetic *eIF4E* allele that mimics natural resistance alleles from different species will retain intrinsic function in translation and shows a broad resistance spectrum in crops in which natural recessive resistance cannot be obtained by conventional breeding. However, it should be noted that the *Arabidopsis* genotype *eIF4E^R/eif4e^{KO}/eifiso4e^{KO}* does not show recessive resistance against all viruses tested. Thus, to control the viruses for which recessive resistance alleles have not been found yet, the identification of natural resistance alleles for these viruses may be necessary.

Conclusions

In this article, we addressed the characteristics of natural recessive resistance found in diverse plant species, the isolation and functional features of recessive resistance genes, and recent advances toward the application of recessive resistance in a wide range of crop species. Indeed, some of the recessive resistance genes summarized in Table 1 are currently utilized to control plant virus diseases in agriculture. Table 1 shows a strong bias toward recessive resistance against RNA viruses, perhaps due partly to research focus. Recent progress in the isolation of recessive resistance genes suggests the continuing relevance of *eIF4Es* as highly dominant recessive resistance genes, as well as the functional diversity of recessive resistance. Further research efforts should explore more diverse classes of recessive resistance genes in the near future. An unexpected regulatory mechanism of natural *eIF4E*-mediated recessive resistance has been proposed, such that a functional *eIF4E1* resistance allele likely negatively regulates *eIF4E2* with redundant functions. Recently emerged genome editing technologies are anticipated to be applied to the molecular breeding of recessive resistance in crops. In particular, the target-AID method will facilitate precise base editing, and is highly suitable for the design of a synthetic resistance allele mimicking natural resistance alleles in a trans-species manner.

As also discussed in this article, genome editing technologies are clearly promising tools for the application of recessive resistance to various crop species. However, social acceptance of genome-edited crops is uncertain in many parts of the world, partly because evidence supporting the safety of genome-edited crops seems to be insufficient due to still developing technologies. Indeed, although some genome-edited crops have been approved without restriction in the USA, the Court of Justice of the European Union decided to make genome-edited crops subject to the same regulations as conventional GM crops. Further basic research is essential to enhance the utility of recessive resistance and support the safety of genome editing technologies for recessive resistance-based crop breeding.

Glossary

Non-persistent manner A mode of virus transmission characterized by short acquisition and inoculation times (from seconds to minutes).

Non-propagative manner A mode of virus transmission in which the virus is not internalized by the vector: the virus is carried externally by attachment to the mouthparts or foregut of the vector.

Pseudo-recombination Component exchange between two geminiviruses. The usual mechanism of pseudo-recombination is by a process known as ‘regulon grafting’: the A component of a virus donates its common region by recombination to the B component of a second virus being captured. This results in a new dependent interaction between two components.

Introduction

Estimates of losses as a result of pest or pathogen attack in crop plants are mostly lacking. Whatever meager amount of data is available is not necessarily accurate nor up-to-date. Such data from different countries assessed by different methods should be taken as only a rough estimate. Nevertheless, the available data gives an approximate idea on the tremendous losses to the food and fiber production for the increasing global population.

During 1988–1990 a team of Scientists from Germany, supported by the European Crop Protection Association, published a comprehensive report on pest-induced crop losses on major food and cash crops. In the four principal cereal crops, rice, wheat, barley, and maize, the yield losses due to diseases were in the range of 10%–16% which translates to approx. \$64 billion. When four more crops (potatoes, soybeans, cotton, and coffee) were taken into account the monetary estimate of yield loss increased to \$84 billion, with an estimated harvests worth \$300 billion in 1988–1990. However, this analysis did not cover some important food crops, such as cassava, millet, sorghum, and the horticultural crops, cultivated in developing countries, which are also significantly affected by viral diseases. It was also revealed that the pests and diseases accounted for pre-harvest losses of 42% of the potential value of output during 1988–1990, with 15% due to insect damage and 13% each to weeds and pathogens. An additional 10% of the potential yield was lost post-harvest.

Among different plant pathogens, the fungal pathogens cause maximum damage with an estimated loss of 40%–60%, followed by the viral diseases causing a loss of 10%–15% and the rest of the losses are caused by bacterial pathogens, phytoplasma, and nematodes. The above data should be cautiously interpreted, as such survey data are mere rough estimates and probably the selection of crops was different and fewer viral diseases were considered. In several crops the yield losses caused by different viral diseases can range from 0% to 100% (Table 1). For example, in one of the surveys conducted in eight African countries, the yield losses because of cassava mosaic disease (CMD) were estimated to be in the range of 30%–40%. Barley yellow dwarf viruses (BYDVs) has a global distribution and infect over 150 species of the family Poaceae, including staple cereals such as wheat, barley, oats, rye, rice, and maize. A number of studies have demonstrated the devastating effect these viruses may have on cereals and the seed yield reductions are in the range of 15%–40% depending on the virus isolate and the cereal crop species.

The economic impact caused by viral diseases is not reduction in yield alone, but also deterioration in the quality of the plant produce, such as deformations in peaches affected by Plum pox virus (PPV) or squash with Zucchini yellow mosaic virus (ZYMV) infection. In addition, major economic aspects to be considered are the expenses incurred in production of virus-indexed propagation material, eradication programs, control of insect vectors, and breeding for resistance to viruses. The viral epidemics and the subsequent economic impact are more prominent in tropical and subtropical regions with continuous vegetation round the year, which enables persistence and proliferation of the viruses and their vectors. In contrast, continuous herbaceous vegetation is interrupted during winters

Table 1 Estimated yield or monetary losses due to viral diseases in different crop plants

<i>Crop</i>	<i>Country/Region</i>	<i>Viral name (Acronym)</i>	<i>Virus taxonomy (Genus/Family)</i>	<i>Monetary/Yield losses</i>
<i>Cereals</i>				
Barley, oat, and wheat	Worldwide	Barley yellow dwarf viruses (BYDVs)	<i>Luteovirus/Luteoviridae</i>	Up to 50% yield loss
Maize	Worldwide	Cereal yellow dwarf viruses (CYDVs)	<i>Polerovirus/Luteoviridae</i>	11%–12% yield loss
	Africa	Maize streak virus (MSV)	<i>Mastrevirus/Geminiviridae</i>	17%–71% yield loss
	USA	Maize dwarf mosaic virus (MDMV)	<i>Potyvirus/Potyviridae</i>	42%–75% yield loss
Rice	South and South East Asia	Rice tungro bacilliform virus (RTBV) and Rice tungro spherical virus (RTSV)	<i>Tungrovirus/Caulimoviridae</i>	US\$1.5 billion
	Africa	Rice yellow mottle virus (RYMV)	<i>Waikavirus/Secoviridae</i>	
	South America	Rice hoja blanca virus (RHBV)	<i>Sobemovirus/Solemoviridae</i>	84%–97% yield loss
Wheat	USA	Wheat streak mosaic virus (WSMV)	<i>Tenuivirus/Phenuiviridae</i>	25%–50% yield loss
			<i>Tritimovirus/Potyviridae</i>	27%–75% yield loss
<i>Root and Tuber Crops</i>				
Cassava	Africa & Indian Subcontinent	African cassava mosaic viruses (ACMVs), and East African cassava mosaic viruses (EACMVs)	<i>Begomovirus/Geminiviridae</i>	US\$1.2–2.3 billion per year
Potato	East Africa	Cassava brown streak viruses (CBSVs)	<i>Ipomovirus/Potyviridae</i>	US\$75 million
	Worldwide	Potato leafroll virus (PLRV)	<i>Polerovirus/Luteoviridae</i>	50%–60% yield loss
	UK	Potato virus X (PVX), Potato virus Y (PVY), and Potato leafroll virus (PLRV)	<i>Potexvirus/Alphaflexiviridae</i>	US\$5.5 million
			<i>Potyvirus/Potyviridae</i>	Up to 80% Yield loss
			<i>Polerovirus/Luteoviridae</i>	
	Worldwide	Potato virus X (PVX)	<i>Potexvirus/Alphaflexiviridae</i>	5%–15% yield loss
	Eastern Europe	Potato virus S (PVS)	<i>Carlavirus/Betaflexiviridae</i>	3%–20% yield loss
	Eastern Europe	Potato virus M (PVM)	<i>Carlavirus/Betaflexiviridae</i>	40%–75% yield loss
Sweet potato	Worldwide, East Africa in particular	Sweet potato feathery mottle virus (SPFMoV) and Sweet potato chlorotic stunt virus (SPChSV)	<i>Potyvirus/Potyviridae</i>	50%–90% in combined infections
			<i>Crinivirus/Closteroviridae</i>	
<i>Vegetables</i>				
Cucurbits	Worldwide	Cucumber mosaic virus (CMV)	<i>Cucumovirus/Bromoviridae</i>	10%–20% yield loss
	Worldwide	Zucchini yellow mosaic virus (ZYMV)	<i>Potyvirus/Potyviridae</i>	Up to 100% yield loss
Tomato	Worldwide	Tomato yellow leaf curl viruses (TYLCVs)	<i>Begomovirus/Geminiviridae</i>	93%–100% yield loss (in Jordan)
	Worldwide	Tomato leaf curl New Delhi virus (ToLCNDV)	<i>Begomovirus/Geminiviridae</i>	93%–100% yield loss (in Jordan)
	Worldwide	Tomato spotted wilt virus (TSWV)	<i>Orthotospovirus/Tospoviridae</i>	US\$1 billion in 1994
<i>Fruits</i>				
Banana	Worldwide	Banana streak viruses (BSVs)	<i>Badnavirus/Caulimoviridae</i>	Up to 82% yield loss
	Worldwide	Banana bunchy top virus (BBTV)	<i>Babuvirus/Nanoviridae</i>	US\$50 million in India during 2007–2010
	Asia	Banana bract mosaic virus (BBRMV)	<i>Potyvirus/Potyviridae</i>	30%–70% in India & Philippines
Cacao	Africa	Cacao swollen shoot viruses (CSSVs)	<i>Badnavirus/Caulimoviridae</i>	up to 100% yield loss
Citrus	Worldwide	Citrus tristeza virus (CTV)	<i>Closterovirus/Closteroviridae</i>	Since 1919, 80 million citrus trees eradicated
Grape	France	Grapevine fanleaf virus (GFLV)	<i>Nepovirus/Secoviridae</i>	US\$100 million
Papaya	Worldwide	Papaya ring spot virus (PRSV)	<i>Potyvirus/Potyviridae</i>	Up to 70% yield loss
Stone fruits	Worldwide	Plum pox virus (PPV)	<i>Potyvirus/Potyviridae</i>	US\$10 billion during 1976–2006
<i>Legumes</i>				
Groundnut	Africa	Groundnut rosette virus (GRV)	<i>Umbravirus/Tombusviridae</i>	US\$100 million
		Groundnut rosette assistor virus (GRAV)	<i>Unassigned/Luteoviridae</i>	
	India	Groundnut bud necrosis virus (GBNV)	<i>Orthotospovirus/Tospoviridae</i>	US\$89 million
	India/West Africa	Peanut clump viruses (PCVs)	<i>Pecluvirus/Virgaviridae</i>	US\$38 million
Legumes	Worldwide	Bean yellow mosaic virus (BYMV)	<i>Potyvirus/Potyviridae</i>	US\$300 million (in India)
Pigeonpea	India	Pigeonpea sterility mosaic viruses (PPSMVs)	<i>Emaravirus/Fimoviridae</i>	US\$300 million
Soybean	Worldwide	Soybean mosaic virus (SbMV)	<i>Potyvirus/Potyviridae</i>	8%–25% yield loss

Table 1 Continued

<i>Crop</i>	<i>Country/Region</i>	<i>Viral name (Acronym)</i>	<i>Virus taxonomy (Genus/Family)</i>	<i>Monetary/Yield losses</i>
<i>Cash Crops</i>				
Cardamom	India	Cardamom mosaic virus (CarMV)	<i>Macluravirus/Potyviridae</i>	70%–100% yield loss
Cotton	India/Pakistan	Cotton leaf curl viruses (CLCVs)	<i>Begomovirus/Geminiviridae</i>	68%–71% yield loss US\$5 billion in Pakistan, during 1992–1997
Sugarcane	Worldwide except Guyana and Mauritius	Sugarcane mosaic virus (SCMV)	<i>Potyvirus/Potyviridae</i>	30%–80% yield loss
Tobacco/ Tomato	Worldwide	Tobacco mosaic virus (TMV)	<i>Tobamovirus/Virgaviridae</i>	~1% yield losses in Tobacco and Up to 20% in Tomato

in the temperate regions and also in arid regions with dry hot summers, impacting negatively the vector population and subsequent virus transmission is significantly reduced. Furthermore the spread and prevalence of viral diseases is much higher in plants that are vegetatively propagated, such as cassava, potato, and citrus, than in those that are propagated through seeds. With a few exceptions, a majority of viruses are not seed transmitted, because of lack of vascular or the plasmodesmatal connection between the embryo and its parent plant. In vegetatively propagated plants, when the seed tubers, cuttings, bud wood, bulbs, runners, *etc.*, are derived from infected plants viruses are transmitted to the subsequent generations. This is in addition to spread of the virus by vectors, which may occur in both cases. In the last two decades the whitefly transmitted viruses have been on the raise in several crops, including vegetables, often becoming a major constraint of production. In this article, it is not possible to cover the economic impact of all plant viral diseases, however we have made an effort to highlight the impact of most important virus diseases on economically important crops (**Table 1**).

Cereal Viral Diseases

Globally wheat is cultivated in an area of 218 mHa with a total production of 772 mt. Diseases caused by viral pathogens are the major threat to early planted wheat in the southern Great Plains of United States (USA). The Wheat streak mosaic virus (WSMV, genus *Tritimovirus*, family *Potyviridae*) transmitted by wheat curl mite causes grain and forage yield losses that significantly affect profits from wheat production. The yield losses in wheat crop due to WSMV ranged from 27% to 75%. WSMV shows synergistic interactions with other viruses (specifically Triticum mosaic virus and High plains virus), further contributing to yield reductions. WSMV infects some of the most agriculturally important members of the family Poaceae, including wheat, corn, rye, oats, barley, sorghum, millets, and the grassy weeds that may act as alternate hosts. Barley yellow dwarf virus (BYDV; genus *Luteovirus*, family *Luteoviridae*), transmitted by aphids, is another important virus known to infect economically important crops such as barley, oats, wheat, maize, triticale, and rice. The yield losses caused by BYDV infection can vary widely depending on the viral strain, time of infection and rate of spread. Maximum yield losses up to 50% occur from early infections. Brome mosaic virus (BMV, genus *Bromovirus*, family *Bromoviridae*) is another economically important virus infecting barley and other cereal crops. BMV is also known to co-infect triticale along with WSMV. As per a study conducted in Ohio (USA), BMV could reduce the yield by as much as 61% in soft red winter wheat.

Corn cultivated in a global area of 197 mHa, is also affected by more than 25 viral diseases. The total estimated corn loss (bushels) by different viral diseases in the United States and Canada, during 2012–2015 was estimated to be 23.6 million bushels and of this ~46% was by Maize dwarf mosaic virus (MDMV, genus *Luteovirus*, family *Luteoviridae*) alone. Maize streak virus (MSV; genus *Mastrevirus*, family *Geminiviridae*) transmitted by six leafhopper species, is one of the most devastating viruses that occurs throughout Africa on corn. MSV epidemiology is controlled by environmental conditions on its vector, resulting in epidemics every 3–10 years. During the epidemic years, disease incidence can vary from a few infected corn plants per field, with little associated yield loss, to 100% infection rates and complete yield loss (**Fig. 1**).

Root and Tuber Crops Viral Diseases

Cassava Viral Diseases

Cassava is an important food security crop for small holder and marginal farmers of developing countries. Cassava is a climate resilient crop with exceptional drought tolerance and is a staple food for close to one billion people in the tropics. Globally, cassava is cultivated in an area of 26 mHa, with a total production of 292 mt and of this total area, 76% area is in African continent itself accounting for a total production of 178 mt. However, because of its vegetative propagation, cassava is affected by at least 20 different viruses worldwide. In sub-Saharan Africa, these viruses are persistently posing a big threat to food security, and resulting in a monetary loss of more than \$1 billion annually. In particular, the two groups of whitefly transmitting cassava infecting viruses, namely begomoviruses (genus *Begomovirus*, family *Geminiviridae*) with single strand DNA (ssDNA) as their genome and Cassava brown streak viruses (genus *Ipomovirus*, family *Potyviridae*) with single strand RNA (ssRNA) as their genome,

have been responsible for the severe pandemics in Africa. The cassava infecting geminiviruses cause cassava mosaic disease (CMD) and the cassava infecting ipomoviruses cause cassava brown streak disease (CBSD). Currently, eleven distinct species of begomoviruses are involved in CMD, of these 9 are reported from Africa and 2 from the Indian subcontinent. In Africa, these 9 begomoviruses can be broadly categorized into African cassava mosaic viruses (ACMVs) and East African cassava mosaic viruses (EACMVs). ACMV and EACMV-like viruses can either occur singly or as mixed infections causing more severe symptoms. The yield losses in different cassava cultivars, in different African countries range from 20% to 95%. Estimates done in mid-1990s, revealed that the yield losses in the entire African continent was 12–23 mt of fresh edible roots per year, worth about \$1.2–2.3 billion. Starting from 1988 till date, an unusually severe form of CMD pandemic is spreading across East and Central Africa, affecting food supplies and creating a famine in Uganda in the late 90s. In 1999, this CMD pandemic had affected at least nine countries in East and Central Africa, encompassing an area of 2.6 million square kilometers and causing an estimated loss of \$1.9–2.7 billion per year. This severe form of CMD has been attributed at first to a recombinant strain of cassava mosaic virus. Later studies revealed that synergistic interactions between ACMV and a Ugandan strain of EACMV on mixed infection was mainly responsible for this severe form of CMD. The local cassava cultivars were highly susceptible to this recombinant strain and due to heavy losses many farmers abandoned cassava cultivation, resulting in destabilization of food security in Uganda. It was estimated that each year an area of c. 60,000 ha of cassava yielding 600,000 t of edible roots worth \$60 million was lost due to CMD. Thus CMD was considered as the most damaging plant viral disease in the world, causing famine and death of thousands of people in Uganda which lost 90% of its production by 1998.

In 2010, the Science journal published a report on seven most dangerous plant diseases in the world that can significantly affect the food security. Of all the plant diseases, CBSD was the only viral disease to be listed in this report. Although the first report of CBSD was made in 1930s from coastal region of Tanzania, in contrast to CMD, CBSD received much less attention, since it was restricted to the coastal low lying areas of East Africa, it appeared sporadically and did not cause any significant loss. However, post 2004, CBSD has been spreading across East and Central Africa at an alarming rate, with reports of CBSD incidence in highland areas too and hence risking the food security of millions of farmers in Africa.

One of the estimates on incidence of CBSD, by National Agricultural Research Organization (NARO, Uganda), put the overall incidence at 16% in 2008 and 29% in 2009, clearly indicating the rapid expansion of the new CBSD epidemic. Shortly after the reports of spread in Uganda, similar observations were made in western Kenya and the Lake Victoria zone of Tanzania. A survey in 19 districts of Tanzania revealed a steep increase in CBSD incidence from 6% in 2006 to 12% in 2007 and in 2008 it was 32%.

Most of the increase in disease incidence was attributed to greater levels of disease in districts in which CBSD was already present by 2006 (12 of 19 districts).

In addition to the reduced growth of the cassava plants as a result of CBSD infection, significant losses occur due to spoilage of harvested roots due to necrotic rots. There have been very few quantitative assessments of yield losses and one such assessment done in southern coastal Tanzania revealed that the losses could occur to an extent of 70% in susceptible cassava cultivars. As the CBSD infected cassava plants mature, the root symptoms can further increase and hence farmers opt for early harvest to prevent further damage of roots. The effects on roots could be variable, such as: reduction in the quality of roots caused by pitting, constrictions and root necrosis, as well as yield reduction through reduction in the number and weight of tuberous roots. An estimate done in 2001, indicated an overall loss of 20%–25%, equivalent to a monetary value of \$6–7 million. An effort was made to estimate the economic impact due to CBSD in Africa through development of a framework. This revealed that there are some of the undocumented elements of CBSD yield loss, such as additional labor cost incurred to separate necrotic from non-necrotic portions of affected roots and the deleterious effects on starch quality of non-necrotic portions of affected roots. A total loss of \$75 million was estimated for all the eight countries of East and Central Africa affected by CBSD.

For control of both CMD & CBSD, the main emphasis has been on the development of virus resistant cassava cultivars, phytosanitary practices such as using cuttings from healthy plants, elimination of infected plants, and production of virus-free tissue-cultured plant propagules. CMD can also be controlled by introgressing one of these three sources of resistance: polygenic recessive resistance, termed CMD1, the dominant monolocus type, named CMD2, and the recently identified CMD3 locus. Application of pesticides to stop the spread of CMD by controlling the whitefly vectors has not been successful.

Potato Viral Diseases

Globally, potato is one of the major crops cultivated in an area of 19 mHa with a total production of 388 mt per year. Since potato is mainly vegetatively propagated, viral diseases are major constraint for cultivation of potato and the yields are reduced beyond 50%. Since potato is an economically important crop maximum research was devoted to it in the first half of the 20th century. Several new tools and techniques such as, serology, meristem cultures, and advanced microscopy were developed for management of potato infecting viruses. More than 37 viruses are known to naturally infect potato, with Potato virus Y (PVY; genus *Potyvirus*, family *Potyviridae*), Potato virus X (PVX; genus *Potexvirus*, family *Alphaflexiviridae*), Potato leafroll virus (PLRV; genus *Polerovirus*, family *Luteoviridae*), Potato virus S (PVS; genus *Carlavirus*, family *Betaflexiviridae*), Potato virus M (PVM; genus *Carlavirus*, family *Betaflexiviridae*), Potato aucuba mosaic virus (PAMV; genus *Potexvirus*, family *Alphaflexiviridae*), and Potato mop-top virus (PMTV; genus *Pomovirus*, family *Virgaviridae*) being the most economically important and widely spread. Additionally, Potato spindle tuber viroid (PSTVd; genus *Pospiviroid*, family *Pospiviroidae*) also cause major damages.

PLRV, present across the globe, is reported to cause 50%–60% yield losses in potato and this virus is tuber borne and mainly vectored by aphids in a circulative and non-propagative manner. Whenever potato plants are co-infected with PLRV and PVX or PVY, yields are reduced to an extent of 70%.

PVY first described in 1930s, has a global distribution and has been known for several decades as a threat to seed, ware and processed potatoes. In addition to potato it is also known to infect several other host plants in Solanaceae family, such as tobacco, tomato, and pepper, causing yield losses up to 80%. PVY is transmitted by more than 40 aphid species in a non-persistent manner. The isolates of PVY are highly variable at the biological, serological, and molecular levels. Due to lack of source of resistance to PVY and its plant-to-plant transmission through daughter tubers, the main control strategy used is primarily based on certification of seed production. A severe group of PVY strains named as PVY_{NTN} are reported from Europe, Japan, and the US, and cause a severe form of disease in potato. The infected tubers develop superficial rings that later are sunken and necrotic. During storage these necrotic damages often become more conspicuous, and can affect 90% of tubers in susceptible cultivars. In spite of the latest improvements in diagnostic methods, routinely applied methods are unable to accurately characterize isolates responsible for tuber necrosis. Currently there is no serological assay, which can distinguish between PVY_{NTN} and other PVY strains. Hence, there is no efficient means to manage the risks of epidemics caused by the emerging necrotic variants of PVY. The global potato market is worth several billion dollars and highly competitive, with poor understanding of the PVY-host interactions involved in induction of necrotic symptoms and inefficient diagnostic tools have led to a situation in which necrotic strains of PVY can potentially cause huge agronomic and economic losses. Furthermore, when PVY occurs along with PVX the yield losses are much more drastic.

Crop yields can be further reduced by 5%–15% whenever plants are secondarily infected by PVX and PVS. PVM and PVS are common in countries of Eastern Europe. PVM can result in 40%–75% loss in tuber yield and it generally occurs in complex with other viruses (especially PVS). While with infection by PVS isolates tuber yield may be reduced by 3%–20%. Plants propagated from infected stocks, for several generations, may suffer more severe losses. Thus, for example, during the years 1993–1995, potato yields in Kazakhstan were extremely low, averaging 9 t/Ha. In a pilot project funded by USAID, micro-tubers obtained from meristems of potatoes screened for virus, were used, which resulted in a low infection rate in the elite seed tubers. These elite seeds enhance the yields by about 90% when compared with tuber yields from commercial fields in the neighborhood.

Potato yields in erstwhile Soviet Union countries were low, averaging 11 t/Ha during 1993–1995 as there was no reliable system for providing certified virus-free tuber seeds, and farmers used seeds from their own farms. Reduced yields are mostly due to virus diseases carried over in the planting material. Thus, Loshitsky and Belorusky 3N cultivars developed by the Belarusian Research Institute for Potato Growing (BRIP) yielded 30–50 t/Ha in the experimental fields, while Belarus' average potato yields

were in the range of 12.2 and 16.3 tonnes per hectare. Assuming that the viral diseases in potato cause 20% damage, that would be translated to a total loss of 18 mt of potato in former USSR with 6 mHa under potato cultivation, with a total production of 70 mt. For any estimate for monetary implication, it is also important to consider the expenses involved in seed potato certification schemes. The main objective of such schemes is to produce true-to-type disease-free (mainly viruses) potato seed tubers. Such schemes mostly include *in vitro* produced plantlets for the initial increase of pathogen-tested clonal selections, including production of mini-tubers. Price of certified tuber seeds are almost double the price for ware potatoes.

Sweet Potato Viral Diseases

Sweet potato (*Ipomoea batatas*) is cultivated in both tropical and warm temperate regions and is the seventh most important food crop in terms of production. In 2017, globally sweet potato was cultivated in an area of 9 mHa, with a total production of 113 mt, with China as the leading producer. Sweet potato is called 'poor man's crop', since most of the production is done on a small or subsistence level and can be cultivated without much inputs such as fertilizers and irrigation, and is one of the crops that can survive the famines. Sweet potato produces more biomass and nutrients per hectare than any other food crop in the world. Sweet potato is a major crop in East Africa and thousands of villages depend on sweet potato for food supply and the Japanese use it when typhoons demolish their paddy fields. Yields vary greatly in different areas or even fields in the same region. The average yields in African countries is about 4.7 t/Ha, while the yields in Asia are significantly higher, averaging to 18.5 t/Ha. Such large variation in yields is attributed to variation in quality of the propagation material. Sweet potatoes are vegetatively propagated from vines, root slips (sprouts) or tubers, and generally the farmers in African countries use vines from their own fields for propagation year after year. Thus, use of virus infected material for propagation results in reduced yield and often these fields are infected with several viruses, thereby compounding the effect on yields. Some of the viruses that are reported to infect sweet potato are Sweet potato feathery mottle virus (SPFMV; genus *Potyvirus*, family *Potyviridae*), Sweet potato mild mottle virus (SPMMV; genus *Ipomovirus*, family *Potyviridae*), Sweet potato latent virus (SPLV; genus *Potyvirus*, family *Potyviridae*), and Sweet potato chlorotic stunt virus (SPCSV; genus *Crinivirus*, family *Closteroviridae*). Infection by both SPFMV and SPCSV causes the very severe sweet potato virus disease (SPVD) and it is the most important disease of sweet potato in Africa. SPVD can cause 50%–80% yield losses in Uganda and Kenya. In a 3-years field study in Cameroon, SPVD incidence resulted in a yield loss of 56%–90%, especially in the susceptible cultivars. Similarly, 78% yield reductions have been reported from field trials in Nigeria due to SPVD. Yield reduction of 50% were reported from a 2-year field experiment in Israel, in plots planted with SPVD-infected cuttings, while infection by SPFMV or SPCSV alone did not have any significant effect on yield. In China, the average yield losses due to sweet potato viral diseases are of over 20% and the infection rate in the Shandong province can range from 5% to 41%. In countries where virus-free planting material is provided, for instance in the USA and Israel, markedly higher yields of 16.3 and 30 t/Ha respectively, are obtained. Cucumber mosaic virus (CMV) alone does not infect sweet potato plants that are healthy and virus free, however, superinfection by CMV can cause a complete crop failure when sweet potatoes are carrying SPCSV.

Most effective way to control viral diseases of sweet potato is through supply of virus-indexed healthy planting material, which is being practiced in Israel and in the Shandong province of China. Planting virus-tested material increased yields by at least by 100% in Israel, while in China the yield increase ranged from 22% to 92%. In Israel use of certified material costing 3 US cents per cutting, prepared by special nurseries, is a common practice. Initially, farmers buy about 30% of planting material required to plant their fields and later use the cuttings from this to fill in the rest. Yields are high and stable when virus-free material is used. In African countries virus-indexing programs operate only on a limited scale, since sweet potatoes are mainly grown as a food security crop, and not as a commercial one. Resistance breeding programs might be an answer for introgressing SPVD resistance and such programs are in operation in Uganda. One has to see if these improved sweet potato cultivars have stable, durable and broad spectrum resistance. An example for unstable resistance was reported when several clones resistant to SPFMV from the International Potato Center (CIP, Peru) were found to be susceptible when Israeli and Ugandan isolates of SPFMV were used for screening (Fig. 2).

Vegetable Viral Diseases

Chilli Viral Diseases

Chilli or hot pepper (*Capsicum annum* L., family Solanaceae) is economically most important and valuable spice and vegetable crop throughout the world. Chilli is native to New Mexico and the Portuguese introduced chillies in Indo-Pak sub-continent from Brazil in 16th century. India is the world's largest producer, consumer and exporter of chillies in the world, contributing 40% of the total world production. Other major chillies producing countries are China, Bangladesh, and Peru.

Chilli is vulnerable to several pathogens, including the viral diseases and till date 65 viruses are reported to infect chilli resulting in heavy yield losses. Mostly, the viruses are spread or transmitted by infected seeds, insects and or by the mechanical tools. Most of the viral diseases are difficult to diagnose due to significant overlap of symptomatology. Symptoms produced by different viruses are mosaic pattern on leaves, yellowing, ring spots, leaf deformation, curling of leaves, and stunting of plants. Common viral diseases are; Alfalfa mosaic virus, Beet curly top virus, Cucumber mosaic virus, Pepper mottle virus, Tobacco mosaic virus, Chilli leaf curl virus, and Pepper mosaic virus, which are transmitted by aphids and whitefly vectors. Chilli leaf curl viral disease

(ChilCVD, genus *Begomovirus*, family *Geminiviridae*) persistently transmitted by whiteflies, is the most destructive virus disease in terms of incidence and yield loss, causing a yield loss of 53% or more. The disease can be identified by typical upward leaf curling, crinkling, puckering and reduction in leaf area along with stunting of whole plants. It is transmitted by the whitefly *Bemisia tabaci* in persistent manner. The first report of *Chilli leaf curl disease virus* in India was in 1954, which was later reported in frequent intervals. However, after 2005 the virus complex has been emerging rapidly across the Indian subcontinent.

Cucurbit Viral Diseases

Worldwide, cucurbits are known to be infected by large number of viruses causing significant economic losses. Cucurbit viruses represent a complex and changing pathosystem and cucumber alone is affected by at least 153 viruses. Virus infection in cucurbits generally result in three broad categories of symptoms: (1) Mosaic in leaves, often associated with deformations: leaf size reduction, rugosity, and enations; (2) Yellows, generally affecting the older leaves and later spreading to younger leaves, often accompanied by leaf thickening and reduction in fruit production, but not the fruit quality; (3) Necrosis as necrotic spots on leaves or as generalized necrosis resulting in death of plant, that occur in certain virus/strain and host/cultivar combinations, particularly with potyviruses. Fruits generally don't mature and may develop necrotic symptoms. Often in the field there are mixed infections of two or more viruses, that lead to combination of above three symptom types.

Cucumber mosaic virus (CMV, genus *Cucumovirus*, family *Bromoviridae*), transmitted by aphids, known since beginning of 20th century, is the first mosaic disease reported in cucurbits in the U.S. CMV causes most significant economic losses in melon, cucumber and squash, but is rarely found in watermelon. CMV has a broad host range, that infects more than 775 different plant species representing more than 86 different families. Two major CMV subgroups have been identified based on the serological and molecular properties. A diversity of CMV strains are also reported that differ in symptomatology, host range, virulence towards resistance genes, and aphid transmissibility. Epidemics of CMV were found to be very rapid in Southern Europe and generalized in melons, while in zucchini and squash were often slow to develop symptoms and limited to a few plants.

Epidemics are occasionally reported from temperate regions such as north-eastern U.S. or central Europe. Several distinct species of the *Potyvirus* genus (family *Potyviridae*) infect cultivated cucurbits. Three of them, Papaya ringspot virus (PRSV), Watermelon mosaic virus 2 (WMV2), and Zucchini yellow mosaic virus (ZYMV) have a global spread, and cause significant yield reductions in melon, cucumber, squash, and watermelon. Epidemics of PRSV are common in tropical and subtropical regions where the wild cucurbit species act as reservoirs for the virus. While, WMV2 has been reported more than 50 years ago from across the world.

Zucchini yellow mosaic virus (ZYMV) is one of the first cucurbit 'emerging' viruses that threatened the cucurbit industries across the globe in the early 1980s. In addition to mosaic and deformations on leaves and fruits of all cultivated cucurbits, various "bump" shapes are observed on mature fruits, making them unmarketable. First reported from Italy and France, within a decade's time ZYMV has spread to the major cucurbit producing regions of the world. ZYMV has also colonized new regions or islands. Economic effect of the virus can be dramatic, early infections can result in complete yield loss.

LIYV is another major virus prevalent in cucurbits, lettuce, and sugarbeets. Despite the atypical shift in vectors populations, LIYV caused major economic losses due to its prevalence in lettuce, sugarbeets, and melons. In 1981 alone, the estimated losses were US\$20 million. Squash leaf curl virus (SCLV) and Watermelon chlorotic stunt virus (WmCSV) are transmitted by *B. tabaci* in a persistent manner are two other important viruses that cause significant damage to cucurbits.

Okra Viral Diseases

Okra or bhendi or ladies finger (*Abelmoschus esculentus*) is an economically important vegetable crop grown in tropical and subtropical parts of the world and India is the leading producers of okra in the world. However, cultivation of okra is constrained by very high incidence of Bhendi yellow vein mosaic virus (BYVMV) disease, transmitted through whitefly. BYVMV infects the crop at all growth stages and causes 50%–100% yield loss, as well as reduction in quality, if the plants get infected within 20 days after germination. In India, Bhendi yellow vein mosaic disease (BYVMD) is one of the most economically important diseases of bhendi/okra and is caused by a monopartite begomovirus Bhendi yellow vein mosaic virus (BYVMV; genus *Begomovirus*, family *Geminiviridae*) associated with Bhendi yellow vein betasatellite (BYVβ). The first report of BYVMV was from Mumbai in 1924.

Tomato Viral Diseases

Globally, tomato (*Solanum lycopersicum*) is cultivated in an area of 4.8 mHa, with a total production of 182 mt and with an estimated value of over \$40 billion in 2017. In terms of economic value, tomato shares approx. 70% of the total value of fresh vegetables produced worldwide. At least 136 different viruses are known to infect tomato, whereas this number is significantly lower for other vegetable crops, for example, 49 viruses are reported to infect pepper (*Capsicum annuum*), 46 infect melon (*Cucumis melo*), 53 infect lettuce (*Lactuca sativa*), 54 infect potato (*S. tuberosum*), and 44 infect eggplant (*S. melongena*). Only cucumber (*C. sativus*) is infected by more viruses than tomato (153).

Years of intensive breeding for yield enhancement in tomato, ignoring the resistance traits has reduced the genetic base for virus resistance in cultivated tomato. Further intensified cultivation of tomato, with large areas under tomato mono-cropping might have favored proliferation of tomato viruses and their vectors. *Begomoviruses* and other whitefly-transmitted viruses are invading into new regions, and other emerging viruses such as new tospoviruses and Tomato torrado virus (ToTV; genus *Torradovirus*, family *Secoviridae*) are rapidly spreading over larger geographic areas. In this article, we will restrict to economic impact caused by tomato leaf curl begomoviruses and Tomato spotted wilt virus (TSWV).

The spotted wilt disease of tomatoes was first reported from Australia in 1915 and later demonstrated to be caused by a virus and transmitted by thrips. The causative agent, was named as Tomato spotted wilt virus (TSWV; genus *Tospovirus*, family *Bunyaviridae*). TSWV causes a range of symptoms, such as chlorotic/necrotic rings and flecking on leaves, stems and fruits. Early infection of TSWV can lead to one-sided growth, drooping of leaves reminiscent of vascular wilt, and stunting or death of the tomato plant. Subsequently, these infections produce unmarketable fruits with conspicuous chlorotic/necrotic ringspots. Control of the TSWV vector thrips is almost impossible due to their high fecundity, propensity to develop insecticide resistance and due to their vast host range. TSWV can replicate within the thrips vectors, which is a characteristic feature of many membrane-bound bunyaviruses. The worldwide dispersal of the TSWV vector Western flower thrips (*Frankliniella occidentalis*) resulted in re-emergence of TSWV as a major agricultural pathogen in 1980s. In 1994, the monetary losses by menace of TSWV, across the globe was estimated to be over \$1 billion annually. Till date TSWV is considered to be economically the most important virus due to its global presence and a broad host range with ability to infect more than 800 plant species, including tomato, pepper, lettuce, peanut, and chrysanthemum.

Tomato yellow leaf curl disease (TYLCD) is another major constraint for cultivation of tomato. TYLCD is widely distributed in Asia, sub-Saharan Africa, the Caribbean Islands, Australia, and the USA. More than 57 different geminivirus species generally called as Tomato yellow leaf curl virus (TYLCV, genus *Begomovirus*, family *Geminiviridae*) are reported to infect tomato. In the United States the whitefly-transmitted geminiviruses (WTGs) appeared first in early 1990s, accounting for 20% estimated yield loss. Whereas in the Latin American countries, namely, Brazil, Cuba, Guatemala, Mexico, and Costa Rica, yield losses were in the range

Fig. 3 Characteristic symptoms of important vegetable viral diseases: (A) Tomato yellow leaf curl virus (TYLCV) on tomato, (B) Tomato spotted wilt virus (TSWV) on tomato fruits, (C) Tomato spotted wilt virus (TSWV) on tomato leaf, (D) Okra yellow vein mosaic virus (OYVMV) on okra, (E) Chilli leaf curl disease (ChLCD) on chilli, (F) Zucchini yellow mosaic virus (ZYMV) on *Cucurbita pepo*, fruits (left) and leaf (right). (A) Source: <https://plantpath.ifas.ufl.edu/plant-virus-profiles/images/Picture1.jpg>. (B) Source: Whitney Cranshaw, Colorado State University, Available at: Bugwood.org. of 30%–100%. The estimated losses during 1989–1995 in Dominican Republic were to the level of \$50 million. Another study has revealed that the Tomato leaf curl viruses (ToLCVs) cause an annual yield loss of \$140 million in Florida, USA. Although it is possible to chemically control the whiteflies, but this may not be possible when there are large population sizes of whiteflies. However, under protected cultivation, physical barriers such as greenhouses enveloped by net screens are effective, while ‘floating barriers’ of perforated polyethylene sheets stretched over tomato fields prevent the landing of whiteflies. Such measures, increase the costs of cultivation and it may be difficult for small and marginal farmers to take up such protected cultivation. Hence, cultivation of virus resistant/tolerant tomato varieties is economically more feasible and breeding programs for introgression of virus resistant traits are in progress.

Tomato leaf curl New Delhi virus (ToLCNDV) (genus *Begomovirus*, family *Geminiviridae*) is a major constraint in tomato production and is economically most important disease affecting tomato in Indian subcontinent. The first report of association of ToLCNDV with tomato leaf curl disease on solanaceous crops was from India in 1995. However, in the last few years ToLCNDV has significantly widened its host range and has moved to new geographical areas, including the Middle East, the western Mediterranean Basin, and some of the European countries. Recombination and pseudo-recombination are the major factors for diversification and adaptive evolution of ToLCNDV. Emergence and epidemics of ToLCNDV has resulted in increased yield losses in several important crops, including tomato. Recent reports from Tunisia, Italy, and Spain indicate infection of ToLCNDV isolates in several cucurbit species. Sequence analysis revealed that a novel strain of ToLCNDV (ToLCNDV-ES) is spreading in the western Mediterranean region, which probably evolved through recombination from a highly diverse population of ToLCNDV. Several reports have demonstrated the involvement of monopartite begomoviruses in the major disease complexes affecting various crops in the “Old World”. However, ToLCNDV a bipartite begomovirus is the only exception to this, which causes diseases in a number of plant species of the families Solanaceae, Cucurbitaceae, Euphorbiaceae, Fabaceae, and Malvaceae. Furthermore in addition to vegetable crops, ToLCNDV has been reported to cause damage to fiber crop species and was also found to infect a number of weeds. Currently, ToLCNDV is known to infect 43 different plant species in Bangladesh, India, Indonesia, Iran, Italy, Malaysia, Pakistan, Sri Lanka, Spain, Taiwan, Thailand, and Tunisia. Co-existence of satellite DNAs (betasatellites) along with ToLCNDV is also reported from natural infections and are known to modulate its pathogenesis, including host range (Fig. 3).

Fruit Virus Diseases

Banana Viral Diseases

Banana is an important source of carbohydrate and is cultivated in more than 130 countries. Banana is also a major source of income for millions of farmers from tropical regions of the world. In 2017, total global area under banana cultivation was 5.6 mHa, with a total production of 114 mt. The Asian continent has the largest area under banana cultivation with more than 50% share in total world area. In 2011, the total export value of banana was estimated to be \$895 million. Banana is propagated vegetatively through the use of suckers and this practice has been one of the main cause for outbreaks of several diseases and pests around the world, especially the viruses. At least 20 different viral species belonging to five different families are known to infect banana globally. The economically most important viruses are: Banana streak viruses (BSVs; genus *Badnavirus*, family *Caulimoviridae*), Banana bunchy top virus (BBTV; genus *Babuvirus*, family *Nanoviridae*), Banana bract mosaic virus (BBRMV; genus *Potyvirus*, family *Potyviridae*), and Cucumber mosaic virus (CMV, genus *Cucumovirus*, family *Bromoviridae*).

Worldwide, Banana bunchy top disease (BBTD) is the most devastating disease caused by BBTV and transmitted by the aphid vector *Pentalonia nigronervosa*. This disease was first reported in 1889 from Fiji and an outbreak of BBTD occurred in 1953 resulting in loss of 641,000 bunches. Later, BBTD has spread to more than 36 countries in South Pacific, Asia, and Africa. However, there are no records of BBTD in the New World except in Hawaii (USA). In the 1920s, due to the bunchy top disease epidemics, the Australian banana industry in New South Wales had collapsed, and the total area under banana cultivation was reduced by 90%. Similarly, in Southern Queensland banana production was reduced by more than 95%. In India, BBTD is known to cause heavy losses. One of the most significant BBTD outbreaks was in highly prized hill banana cv. Virupakshi, in the state of Tamil Nadu (India), which reduced the cultivation area from 18,000 to 2,000 Ha. Several epidemics of BBTD during 2007–2010 in Koduru, Andhra Pradesh, and Jalgaon, Maharashtra, India, led to an annual loss of \$50 million. An outbreak of BBTD in Pakistan led to huge reduction in area under banana cultivation from 60,000 to 26,000 Ha. None of the farmer's cultivated banana varieties are resistant to BBTV and production of disease-resistant bananas by conventional breeding is very difficult. Hence, transgenic development of BBTV resistant bananas is the most viable option to achieve resistance to BBTD.

Banana streak disease caused by Banana streak virus (BSV) is also one of the important viral disease of banana which has a wider presence in banana plantations throughout the world. The streak disease was first observed in the Nieky Valley on the Ivory Coast in 1958 and later it was reported from Morocco where almost every established plantation was affected. Banana streak disease is now reported to occur in over 43 countries of Africa, Asia, Australia, Europe, Oceania, and tropical America.

Another viral disease called Banana bract mosaic disease, caused by the Banana bract mosaic virus (BBRMV), was first reported in most of the banana cultivars, from Philippines (island of Mindanao) in 1979 and thought to be different from all other recognized viruses of banana. Later, it was found widespread in entire Philippines. Subsequently the banana bract disease was discovered in other Asian countries including India, Sri Lanka, Samoa, Thailand, and Vietnam. In Latin America, BBRMV was first reported from Colombia. However, there are limited reports available on the economic impact of the disease. In 1997, up to 40% yield losses were reported from Mindanao island of the Philippines. Yield losses in the range of 30%–70% are also reported from India and the Philippines.

Cacao Swollen Shoot Disease

Cacao swollen shoot disease (CSSD) caused by Cacao swollen shoot virus (CSSV; genus *Badnavirus*, family *Caulimoviridae*), was first reported from Ghana in 1936 and is endemic to West Africa covering Togo, Ivory Coast and Nigeria. CSSD is semi-persistently transmitted by mealy bug (*Planococcoides njalensis*) vectors and this disease reduces cacao yield in first year of infection by almost 25%, in second year the yields are reduced by 50%, and in next 3–4 years the tree dies from die back. CSSD economically most important disease, since cacao has high industrial value and this disease has resulted in drastic reduction in cocoa production in Ghana. Since its first report in 1936, more than 200 million cacao trees have been eradicated from about 130,000 Ha. Yield of cacao bean were reduced by 86% during 1945–1950. In 1953, the 50 million diseased trees represented a capital depreciation of £25 million since the report of CSSD. During 2006–2010, over 28 million infected trees were removed and globally today CSSV is responsible for 15% of total cacao crop loss. This disease caused much rural disconnect and political uproar in Ghana. In response to the menace caused by CSSD, Ghana has launched one of the most ambitious eradication program with high investments. In the late 1940s, the British colonial authorities in Ghana enforced an eradication policy for removal of infected cacao trees. This met with a serious opposition, resulted in the rise of a political party led by Kwame Nkruma, who accused the authorities of attempting to destroy farmers' income.

Some of the strategies employed to control this disease are: use of insecticides, biological control of the mealybugs, breeding for resistant cocoa cultivars, and cross-protection with mild strains of CSSV, but the main practice is to rogue the infected and adjacent trees. CSSV has several alternate hosts, such as *Cola gigantean*, and mere removal of infected trees would not solve the CSSD menace and it is important to remove the alternate hosts too.

Citrus Tristeza Virus

Citrus tristeza virus (CTV) (genus *Closterovirus*, family *Closteroviridae*) is the causal agent of devastating epidemics that changed the course of the citrus industry. There are mainly three distinct syndromes caused by CTV, named as tristeza, stem pitting (SP), and

seedling yellows (SY), which is due to differential interaction of CTV with different scions and rootstocks from different regions. Tristeza disease is a decline syndrome caused by infection of CTV on different citrus species such as sweet oranges, mandarins, grapefruits and limes, which are propagated on rootstocks derived from sour orange or lemon.

During 1940–1960, about 30 million citrus trees grafted on sour orange rootstocks were lost in Argentina and Brazil. In 1980s, about 6.6 million trees were lost in Venezuela, and ~10 million trees were lost in Florida and other Caribbean countries. In these regions CTV is mainly transmitted by the brown citrus aphid, *Toxoptera citricida*. In Spain alone CTV took a toll of 10 million citrus trees and several million more were lost in California (USA), Israel, and other areas. In these areas CTV is being spread by the melon aphid, *Aphis gossypii*. In the presence of both the aphid vectors, the spread of CTV is greatly enhanced, as in the case of Florida (USA). Significant yield losses have been documented from several regions and the monetary losses have been estimated. However, these estimates do not include the expenses incurred on removal of dead trees and replanting with healthy plants. Despite the loss of millions of citrus trees in Brazil and Spain, in the long run the citrus production was not affected. In Brazil, in a span of about 40 years, the citrus production increased from 1.7 to 20 mt in 1990s. This would not have been possible without replanting new orchards on tolerant rootstocks, along with budwood control.

Some of the strategies employed for control of CTV damage are quarantine and budwood certification programs, rouging of infected trees, use of tristeza-tolerant rootstocks, or cross protection with mild isolates. The choice of the management practice mostly depends on CTV incidence, the virus strains present and host varieties cultivated in an area. Introgression of virus resistance genes into cultivated genes through conventional breeding is not feasible, while genetic engineering for virus resistance has given variable results. Long distance spread of CTV occurs through movement of infected planting material and then short distance local transport is facilitated by different aphid species and is not known to be seed transmitted. Infection of CTV is mostly restricted to species of two genera of Rutaceae family and the virus is then localized to the phloem cells. The most devastating epidemics of CTV occurred in Argentina (1930), Brazil (1937), California (1939), Florida (1951), Spain (1957), Israel (1970), and Venezuela (1980). Outbreaks of tristeza have also been reported from Cyprus (1989), Cuba (1992), Mexico (1995), the Dominican Republic (1996), and Italy (2002).

In addition to loss of trees, CTV is also indirectly associated with loss of sour orange root stocks with very good agronomic traits. Further, the use of tristeza-tolerant rootstocks has led to the emergence of new problems such as damage from soil salinity or alkalinity, waterlogging, or vulnerability to soil fungi or graft-transmissible pathogens such as citrus blight, Citrus sudden death-associated virus or Citrus tatter leaf virus. Regardless of the rootstock used, the affected trees showed stunting, SP, low yield and poor quality of fruits. Isolates of CTV causing SP, that were initially restricted to regions of Asia, Australia, South Africa, and South America, were subsequently reported from California, Florida, and the Mediterranean region, although at lower frequency.

Implementation of mandatory certification program for maintenance and distribution of virus-free material for commercial use is the best way to control CTV or any other graft transmissible disease. One such publicly operated self-supportive program called 'clean stock program' in Florida charge a fee of \$2 for registration of validated or parent trees. Cross-protection is widely practiced in Brazil, Australia, and South Africa. In particular, this has been highly successful in Brazil for CTV strains causing SP on sweet orange and grapefruit. By 1980, over 8 million trees of Pera sweet orange were cross-protected in Brazil and this is still practiced. In California, an eradication program for tristeza is in place and during 2000–2001 the Central California Tristeza Eradication Agency surveyed approximately 31,400 acres of citrus orchards and carried ELISA tests for about 375,000 individual plants. Undoubtedly this program deferred the spread of tristeza, but huge costs were incurred to remove the sick trees. In Israel, during 1970–1977, a tristeza suppression program was in place, wherein about 300,000 tests were made using indicator plants and electron microscopy and eventually 1700 trees diagnosed with CTV infection were removed. Later in 1979–1980, indexing of 1.25 million of citrus trees by ELISA revealed CTV infection in only 0.13% of the tested trees. Hence such eradication programs delayed the outbreak of a citrus tristeza pandemic in Israel by 15–20 years.

Eighty-five years of epidemics of CTV have made a devastating economic impact on the citrus farms and the industries dependent on it. Worldwide, CTV has taken a toll of more than 80 million citrus trees, mostly in South Africa since 1910, Argentina (10 million) and Brazil (6 million) since 1970, and the US. (3 million) since 1950. Dispersal of CTV is a continuous process and it is feared that the future losses from tristeza may be much more than the losses that have occurred till date. There is also a rapid dispersal of the CTV vector *T. citricida* in Mexico and the Mediterranean basin, with large area under citrus cultivation using the sour orange rootstock, could facilitate the spread of tristeza. The replacement of declining citrus trees with new trees on tristeza tolerant rootstocks can only restore the production of citrus. In the last 40 years, new isolates of SP are being periodically reported in new regions and is going to be a more enduring problem. Cross-border movement of new citrus varieties has resulted in invisible spread of severe SP isolates and is likely to continue despite the quarantine measures.

Papaya Ring Spot Virus

Worldwide papaya is cultivated in an area of 0.44 mHa with a total production of 13.2 mt and 45% of the total production is contributed by India alone. Several pests and pathogens are known to affect papaya (*Carica papaya*) plants, of which viral diseases are the most damaging ones. Of the several viral diseases Papaya ringspot virus (PRSV, genus *Potyvirus*, family *Potyviridae*) inflicts maximum damage to papaya and has a worldwide presence. Other viruses that are known to infect papaya are geminiviruses causing leaf curl symptoms, Papaya meleira virus (PMeV; Unassigned in the family *Totiviridae*), Papaya mosaic virus (PapMV;

genus *Potexvirus*, family *Alphaflexiviridae*), and Papaya lethal yellowing virus (PLYV; genus *Sobemovirus*, family *Solemoviridae*). PRSV is transmitted by several different aphid species in a non-persistent manner. There are no known resistance genes against PRSV in papaya, but tolerance to PRSV is conferred in a quantitative manner. In 1950s, Oahu island in Hawaii (USA) was the main papaya-growing area, however because of the heavy PRSV infection, papaya cultivation was shifted to fertile lands of Puna district (Hawaii, USA) where PRSV was absent. By 1970s, 95% of Hawaiian papaya were cultivated in Puna, but a potential threat of PRSV outbreak remained, since Hilo was just 30 km away.

In 1992, for the first time PRSV was reported from commercial plantings of papaya in Puna district on Hawaii island. Despite all the efforts to minimize the spread of PRSV, more than 50% of Puna was severely affected by PRSV by 1994. Subsequently the Hawaii Department of Agriculture (HDOA) abandoned all the eradication programs. By 1998, most of the papaya plants in Puna were PRSV infected and papaya production was reduced to about half of the 1992 level (12,000 vs 24,000 t of fruits). In 1992, Puna produced 95% (24,000 t) of Hawaii's papaya; but after the entry of PRSV in that region, the production decreased significantly and by 1998 Puna produced only 75% (12,000 t) of Hawaii's production. Papaya production in Puna was reduced to half in 1998, compared to 1992. Clearly, PRSV had a devastating effect on papaya production in 1998. To maintain its markets, especially in mainland of USA and Japan, Hawaii had to keep up production as much as possible. In addition to significant yield losses, PRSV infection severely affected the quality of the produce and the papaya fruits harvested were of inferior quality.

Transgenic papaya overexpressing the coat protein sequence of PRSV were developed by researchers from University of Hawaii (USA) and released as papaya varieties "SunUp" and "Rainbow". These varieties are now widely cultivated in the Hawaii islands of United States and is the most successful field application of transgenic technology. Since the release of PRSV resistant transgenic papaya, the papaya production in Puna showed an increasing trend, starting from 15,400 t in year 2000 to 18,300 t in 2001. Furthermore, papaya production in Puna accounted for 84% of the production in 2002, compared to the low of 65% in 1999. In 2004, Rainbow accounted for 88% of the total area of papaya in Puna (Hawaii, USA).

Plum Pox Virus (Sharka) Disease of Stone Fruits

Plum pox disease, also called as "sharka" is one of the most devastating viral diseases of stone fruits resulting in huge yield losses and a major economic impact. This disease is caused by Plum pox virus (PPV), a positive ssRNA virus and belonging to the genus *Potyvirus* and family *Potyviridae*. In addition to plums (*Prunus domestica*), PPV also infects other stone fruits such as, peaches (*Prunus persica*), apricots (*Prunus armeniaca*), nectarines (*Prunus persica* var. *nucipersica*), almonds (*Prunus dulcis*), sweet cherries (*Prunus avium*) and tart cherries (*Prunus cerasus*). PPV also infects important ornamental and wild *Prunus* species, including those used in traditional medicine: myrobalan, American plum, dwarf flowering almond, and blackthorn. Further, approx. 60 plant species representing eight families are recognized as experimental host plants of PPV. Nevertheless, PPV also infects plants that are not members of genus *Prunus*.

The first report of sharka disease was from plum orchards in Bulgaria during 1915–1918. During 1932–1960, the disease disseminated to north and east from Bulgaria into Yugoslavia, Hungary, Romania, Albania, Czechoslovakia, Germany, and Russia. Initially, sharka disease was mainly found in plums and apricots and since the 1980s has been reported in peaches. About a decade ago, about 100 million stone fruit trees in Europe were reported to be infected. The susceptible varieties could result in 80%–100% yield losses. In Eastern and Central Europe, susceptible plum cultivars exhibit premature fruit drop and bark splitting, and sweet cherry fruits develop chlorotic and necrotic rings and fruit drop occurs prematurely. Although the fruit trees don't die from PPV infection, but the fruits drop prematurely and are unfit for consumption and marketing due to their bitter taste. In 1968, the estimated yield losses due to sharka disease in Bulgaria was 30,000 t. In last several decades, the fruit drop production was to an extent of 80% in Czech Republic, and there was a drastic reduction in number of plum trees from 18 million to 4 million. During 1998–2002, due to PPV infection, about 69,000 stone fruit trees were removed in Emilia–Romagna region of Italy; and about \$450,000 is spent annually for the removal and replanting of trees. An expenditure of \$17 million was incurred for removal of ~1.5 million trees in Spain during 1988–2008. PPV is predominantly present in south east of France and all the symptomatic trees are eliminated and if infection levels are more than 10%, the entire orchard is destroyed. Such operations have resulted in removal of about 27,000 trees in 1992 and 100 ha of plantations (mainly peach) were eliminated in 1993. During 1973–1990, about 91,000 trees were estimated to be destroyed in France. PPV is transmitted by aphids in a non-persistent manner, however the spread in Europe is mainly due to movement of infected nursery material from the Balkans. Vegetative propagation of host plants is the main cause for efficient dissemination of PPV both locally and globally. General susceptibility of hosts, with scarce resistance sources identified, has largely frustrated international resistance breeding efforts.

For most of the 20th century PPV was limited to Europe, however in the past 20 years PPV infection has been reported from Africa, South & North America, and Asia. Currently almost all the major plum production areas are now affected by PPV at varying degrees. Huge efforts and costs are involved in the control and eradication of PPV in several countries. Though successful in a few cases, such efforts have generally slowed the progression of PPV onslaught, but certainly has not stopped it. In 2006, the combined costs for control of Sharka disease were estimated to be \$10 billion over the past 30 years worldwide. Large number of efforts are made for genetically engineering PPV resistance in plums, resulting in successful field trial of the PPV resistant HoneySweet transgenic plum. Dereglulation and cultivation of HoneySweet transgenic plum in USA, is one of the few example of virus-resistant transgenic crops developed to marketability (Fig. 4).

Legume Viral Diseases

A wide range of legumes (Fabaceae: Papilionoideae) are cultivated across the globe as an important source of proteins. These legume crops are severely affected by a range of viral diseases that result in reduced grain yield, poor quality seeds and increased cost of cultivation for phytosanitary activities and disease control, thus making significant impact on economic losses. The majority of the legume infecting viruses are transmitted by insect vectors, and many of them are also seed transmitted. Viral diseases are the major biotic constraints to legumes production, especially in the tropical and subtropical regions. Cultivated food legumes are vulnerable to infection by at least 150 viruses, belonging to different plant viral genera/families. Begomoviral diseases alone in legumes is known to cause an annual estimated yield losses of \$300 million in India. The economic impact of viral diseases in most important legumes/pulse crops, such as soybean, groundnut, cowpea, pigeonpea, and mungbean are listed in **Table 1**.

Worldwide, about 70 different viral species are reported to infect soybean, of which, Soybean mosaic virus (SbMV; genus *Potyvirus*, family *Potyviridae*), Tobacco ring spot virus (TRSV; genus *Nepovirus*, family *Secoviridae*), Peanut bud necrosis virus (PBNV; genus *Tospovirus*, family *Bunyaviridae*), Tobacco streak virus (TSV; genus *Ilarvirus*, family *Bromoviridae*), Soybean dwarf virus (SbDV; genus *Luteovirus*, family *Luteoviridae*), and some begomovirus species are considered to be economically important. SbMV is reported to cause a yield loss in the range of 8%–50%, and can reach up to 100% in severe outbreaks and when coinfecting with Bean pod mottle virus (BPMV; genus *Comovirus*, family *Secoviridae*), Cowpea mosaic virus (CPMV; genus *Comovirus*, family *Secoviridae*), Abutilon mosaic virus (AMV; *Begomovirus*), and TRSV. Several different begomovirus species are associated with the soybean yellow mosaic disease (SYMD). In India alone, the combined yield losses due to SYMD were estimated to exceed \$300 m in mungbean, black gram, and soybean.

At least 32 viruses are reported to naturally infect groundnut, of which TSWV, PBNV, TSV, Peanut clump virus (PCV; genus *Pecluvirus*, family *Virgaviridae*), Indian peanut clump virus (IPCV; genus *Pecluvirus*, family *Virgaviridae*), PeMoV, PSStV, CMV, and Groundnut rosette disease (GRD) caused by a complex of 3 viral agents, Groundnut rosette assistor virus (GRAV), Groundnut rosette virus (GRV, genus *Umbravirus*, family *Tombusviridae*), and a satellite RNA, are considered to be economically important. GRD is the most damaging disease in sub-Saharan Africa (SSA) and many GRD epidemics were reported from Africa, which has caused enormous crop losses.

Spotted wilt disease of groundnut caused by TSWV, can lead to 100% yield loss and this disease is reported from North and South Americas, several African countries, and Australia. In 1998, a similar disease has been reported from Asia, but was shown to be caused by PBNV, a distinct tospovirus. Groundnut bud necrosis disease (GBND) first reported from India, is also prevalent in Sri Lanka, Nepal, Myanmar, Thailand, and parts of China. GBND is caused by a distinct tospovirus, PBNV (synonym Groundnut bud necrosis virus, GBNV). PBNV also infects mungbean, urdbean, soybean, cowpea, pea, and lablab bean under field conditions.

Stem necrosis disease (SND), previously assumed to be caused by PBNV, was later found to be caused by TSV in India. TSV is known to occur on groundnut in India, Pakistan, South Africa, and Brazil and has a broad host range that includes sunflower (*Helianthus annuus*), soybean, mungbean, black gram, cowpea, and sunnhemp (*Crotalaria juncea*). TSV continues to expand its host range. In year 2000, SND was prevalent in nearly 225,000 Ha of erstwhile Andhra Pradesh state of India, which resulted in crop losses exceeding \$65 million. Peanut clump disease (PCD) is prevalent in India, Pakistan, and West Africa, and the causal virus is referred as IPCV in Indian subcontinent and PCV in Africa, both of which cause indistinguishable symptoms. In 2003, worldwide the economic losses due to PCD was estimated to exceed \$38 million. Both IPCV and PCV, infect pigeonpea and other economically important cereal crops. Since the casual viruses are seed transmissible in groundnut, cereals, and millets, PCD has quarantine importance.

Cowpea is most widely cultivated legume in SSA, and is the second most important food legume after groundnut and more than 80% of cowpea production is from West Africa. More than 140 viruses are reported to infect cowpea and of these 20 viruses are known to be economically important. Except CGMV (Cowpea golden mosaic virus) and CCMV (Cowpea chlorotic mottle virus), all the other cowpea viruses are known to be seed transmitted. Pigeonpea is another important grain legume crops, predominately cultivated in the Indian subcontinent, and also in Southern and Eastern Africa, the Caribbean, and China. About 15 viruses are reported to infect pigeonpea, of these, Pigeonpea sterility mosaic emaravirus (PPSMV, genus *Emaravirus*, family *Fimoviridae*) is most important, followed by the whitefly-transmitted begomoviruses. Sterility mosaic disease (SMD) caused by PPSMV is a serious constraint for pigeonpea cultivation in South Asia, with an estimated annual loss of over \$300 million in India alone.

Of several viruses infecting mungbean and urdbean, yellow mosaic caused by begomoviruses, leaf curl caused by PBNV, and leaf crinkle caused by Urdbean leaf crinkle virus (ULCV) are economically most important. In India, both Mungbean yellow mosaic Indian virus (MYMIV) and ULCV are prevalent in both mungbean and urdbean, and are often synergistic leading to yield losses over 90%.

Viruses that are transmitted through legume seeds serve as primary source of virus in virus ecology and disease epidemiology in cultivated legumes and have quarantine importance. Further the multiplication and spread of insect vectors is facilitated by intensive cropping and changes to cropping patterns as a result of increased irrigation and overuse of pesticides. Occurrence and the drastic expansion of the host range of tospoviruses and TSV in particular are major concerns. Some of the strategies employed for management of legume viruses are: selection and planting of virus-free seeds, modification of agronomic practices, chemical, physical, and biological control of viral vectors, and planting of virus-resistant crop varieties developed through conventional or non-conventional crop improvement strategies (Fig. 5).

Cash Crops Viral Diseases

Sugarcane Viral Diseases

Sugarcane is the largest crop production in the world with more than 1800 mt in 2017 on a surface of nearly 26 mt in the world. Worldwide, sugarcane is affected by diverse number of viruses, mainly because of its vegetative propagation. Sugarcane mosaic disease caused by Sugarcane mosaic virus (SCMV; genus *Potyvirus*, family *Potyviridae*) is economically the most important of all and is seen in almost all the major sugarcane-growing countries. The first report of sugarcane mosaic was in 1892, and was subsequently reported from other countries growing sugarcane, maize, and sorghum, namely, Bangladesh, Indonesia, Thailand, Malaysia, China, the United States, Pakistan, Argentina, Australia, Brazil, Cameroon, Colombia, Congo, Cuba, Denmark, Ethiopia, Egypt, France, Germany, Iran, Israel, Mexico, the Netherlands, and Vietnam. The first report from India was in 1921, since then, it invariably infected all the sugarcane cultivars. During 1914–1916, a severe epidemic of sugarcane mosaic occurred in Argentina, resulting in up to 80% losses in sugar production. Later, this crisis was overcome by replacing susceptible varieties of sugarcane with the resistant ones (POJ varieties) from Indonesia (Java). In mid-1920s, epidemic of sugarcane mosaic threatened the sugar industry in both Brazil and the United States, resulting in severe economic crisis in the sugar industry. Subsequently, the disease was controlled by replacing the susceptible varieties with mosaic resistant hybrids. However, later in 1971–1972, it was revealed in Brazil that the mosaic was found in tolerant hybrids with 100% infection, causing a loss of 18% in susceptible clones. Despite the report of sugarcane mosaic in India, it was ignored initially, however later, it was reported to have severe impact on popular sugarcane varieties in the field. Studies showed that the virus infection significantly reduced the number of millable canes, net CO₂

Fig. 5 Characteristic symptoms of important legume viral diseases: (A) Groundnut rosette disease (GRD) on groundnut (center) and healthy plants (left and right), (B) Bean common mosaic virus (BCMV) on bean leaf, (C) Bean yellow mosaic virus (BYMV) on bean leaf, (D) Bean golden mosaic virus (BGMV) on bean, (E) Mungbean yellow mosaic disease (MYMD) on mungbean, (F) Soybean mosaic virus (SbMV) on soybean. assimilation rate, cane growth parameters and other post-harvest juice quality parameters. Extensive surveys conducted at different sugar factories in Indonesia, revealed that about 30% of sugarcane fields were affected by the mosaic disease.

Sugarcane bacilliform virus (SCBV; genus *Badnavirus*, family *Caulimoviridae*) causing leaf fleck disease in sugarcane was first reported from Morocco and now it shows its presence in all the major sugarcane-growing countries. Studies revealed that the *S. officinarum* clones recorded more than 90% SCBV incidence, and other *Saccharum* species also showed the presence of SCBV. SCBV infection is presumed to have originated from Papua New Guinea (Southeast Asia), the center of sugarcane origin, and from there, it might have spread to other areas through the germplasm movement. SCBV is distributed throughout the world in both tropical and subtropical regions and can result in economic losses in the range of 10%–90% in severely infected crops. *Sugarcane yellow leaf virus* (SCYLV; family *Luteoviridae*) causing yellow leaf disease (YLD) is also one of the major threat to sugarcane cultivation worldwide and the commercial sugarcane cultivars of major sugarcane-growing countries are reported with 100% yield incidence in Florida, Brazil, India, etc.

Ornamentals and Orchids Viral Diseases

In 2004, the global floricultural produce was estimated to be \$75 billion, for which Netherlands, USA and Japan were the major contributors. Virus infections in ornamental plants have enhanced the esthetic value in certain cases as well as have resulted in significant monetary losses in several other cases. One of the first uses of esthetic effects of plant virus infection was the production and marketing of highly valued variegated tulips, infected with Tulip breaking virus. Other popular examples are the attractive mosaic patterns on the leaves of Abutilon infected with Abutilon mosaic virus, the variegated flowers of camellia infected with Camellia yellow mottle virus, and the yellow-veined Japanese honeysuckle infected with Honeysuckle yellow vein mosaic virus. In contrast, there are also hundreds of viruses that are known to infect the ornamental plants and cause severe economic losses. Viral diseases reduce the esthetic value and marketability of ornamental plants. Large scale vegetative propagation through virus infected material such as cuttings, bulbs, and corms has significantly contributed for spread of viral diseases in ornamentals. Tospoviruses transmitted by the thrips are known to cause maximum damage to the ornamental plants and their incidence is increasing year by

year mainly because of international trade and movement of propagative material. TSWV and INSV (Impatiens necrotic spot virus) are the two most important tospoviruses infecting the ornamental plants. In India, Chrysanthemum diseases caused by Chrysanthemum virus B (CVB; genus *Carlavirus*, family *Betaflexiviridae*), Cucumber mosaic virus, Tomato aspermy virus and Gladiolus diseases caused by Cucumber mosaic virus (all three viruses; genus *Cucumovirus*, family *Bromoviridae*) are of economic importance.

More than 30 viruses are reported to infect different orchids in various geographical locations. Orchid viruses generally produce mosaics, ringspots, chlorosis, chlorotic and necrotic sunken patches on the leaves, deformation and a drastic reduction in the size of flowers and overall stunting of the plant. The orchid plants, *Phalaenopsis* and *Dendrobium* in particular, are commercially valuable ornamental plants with a global market. Unfortunately, orchid plants are highly susceptible to viruses such as Cymbidium mosaic virus (CymMV; genus *Potexvirus*, family *Alphaflexiviridae*) and Odontoglossum ringspot virus (ORSV; genus *Tobamovirus*, family *Virgaviridae*), posing a major threat and serious economic loss to the orchid industry worldwide. Among the orchid viruses, CymMV and ORSV are considered most important due to their worldwide occurrence and severity of the symptoms in several orchid genera. They reduce the general vigor of the plant and affect the flower quality, thereby reducing the marketability and incurring severe economic losses. These two viruses also occur naturally as mixed infections in several orchid species (Fig. 6).

Retrotransposons of Plants

M-A Grandbastien, INRAE – French National Research Institute for Agriculture, Food and Environment, Versailles, France

© 2008 Elsevier Ltd. All rights reserved.

This is a reproduction of M.-A. Grandbastien, Retrotransposons of Plants, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00544-6.

Glossary

Env Envelope protein of retroviruses and errantiviruses, containing a transmembrane domain and a host receptor-binding domain, and mediating formation of infectious virions and targeting of host receptor cells.

Env-like Coding domains possessing some features similar to those of the env domains of retroviruses (such as a transmembrane domain), but for which no similar function has been shown as yet; env-like domains are found in addition to the gag-pol domain of many plant LTR retrotransposons.

Gag (group-specific antigen) Nucleic acid-binding protein forming the structural core of the retrovirus virion core and of the cytoplasmic VLP of retrotransposons.

Int Integrase function ensuring the insertion of the double-stranded DNA daughter copy in the genome; also sometimes referred to as endonuclease (endo).

LTR (long terminal repeat) Long sequence found repeated in the same orientation at both ends of retroviruses and LTR retrotransposons and containing promoter and regulatory sequences involved in transcription, that starts in the 5' LTR and terminates in the 3' LTR.

PBS (primer binding site) Short sequence found downstream to the 5' LTR, and involved in the priming of the (–)-DNA strand synthesis during reverse transcription.

PPT (polypurine tract) Short AG-rich sequence found upstream to the 3' LTR, and involved in the priming of the (+)-DNA strand synthesis during reverse transcription

Prot Protease protein involved in the cleavage of the functional proteins units from the (gag) pol polyprotein produced by the retrovirus or the retrotransposon.

RT Reverse transcriptase protein ensuring the synthesis of the double-stranded daughter DNA copy from the RNA template produced by the integrated provirus or retrotransposon; an associate ribonucleaseH (RNaseH) function ensures the concomitant degradation of the RNA template.

VLP (virus-like particle) Cytoplasmic intermediate analogous to the virion core of retroviruses; the VLP is constituted by structural gag proteins associated to two copies of the RNA template, together with enzymatic proteins (RT, int); the reverse transcription of the RNA template is thought to occur within the VLP.

Introduction and General Classification

Transposable elements are ubiquitous mobile DNA sequences found in both prokaryotic and eukaryotic genomes. For a long time, they were considered as 'parasite' DNA, but have now been shown to be major components of plant genomes, where they can represent up to 80% of the bulk of large cereal genomes. Transposable elements, with a few notable exceptions, encode the functions involved in their mobility and are classified into two main classes with radically different transposition mechanisms. Class I elements or retrotransposons transpose via an RNA intermediate that is reverse-transcribed into a daughter copy DNA and re-inserted into the genome, while class II elements or DNA transposons move directly from DNA to DNA. Retrotransposons thus belong to the large class of reverse-transcribing elements (or retroelements) that multiply by transferring their genetic information from RNA to DNA, and are close relatives to viral entities such as animal retroviruses or pararetroviruses infecting both animal and plant hosts. However, in contrast to true infectious viruses, which propagate only functional genomes, retrotransposons are vertically transmitted intrinsic components of host genomes. Their integrated genomes are thus submitted to evolutionary drift, with various mutations and restructurations destroying their functionality, and defective copies can still be amplified, sometimes at surprisingly high levels, via functional related copies. Plant retrotransposons are thus found in a tremendous variety of structural variants, including highly defective and deleted versions, making their classification a difficult task. In addition, retrotransposons are composed of modules that frequently show incongruent phylogenies, and this intrinsic chimerical nature often obscures classifications based on phylogenies.

There are two main categories of retrotransposons: LTR retrotransposons that contain two long terminal repeats (LTRs), and non-LTR retrotransposons often referred to as retroposons. All functional copies encode as basic modules the structural and functional proteins required for the retrotransposition cycle (summarized in Fig. 1). These include a structural RNA-binding protein (gag or gag-like), and a pol domain encoding the reverse transcriptase (RT) ensuring the synthesis of the double-stranded daughter DNA copy from the RNA template, as well as in most cases a protein ensuring insertion of the double-stranded DNA daughter copy in the genome (referred to as integrase for most elements). A number of plant LTR retrotransposons contain an additional coding domain currently termed env-like, although, as discussed below, functional and structural analogies to retroviral env proteins remain to be demonstrated.

LTR retrotransposons have been further classified in Ty1/*copia*-type elements and Ty3/*gypsy*-type depending on the order of the coding domains. Non-LTR retrotransposons include LINEs (long interspersed nuclear elements), which are elements carrying

Fig. 1 Structural diversity of retrotransposons found in plant genomes. The structure of a retrovirus has been provided for reference. The gag and pol domains are encoded in one or two frames, depending on the element, and have been represented here as a single ORF for simplification. Family names are indicated on the left and genus names on the right. LTR, long terminal repeat; gag, nucleic acid-binding protein forming the structural core of the retrovirus virion core and of the cytoplasmic VLP of retrotransposons; prot, protease protein involved in the cleavage of the functional proteins units from the (gag) pol polyprotein; int, integrase function ensuring the insertion of the double-stranded DNA copy in the genome; RT, reverse transcriptase ensuring the synthesis of the double-stranded DNA copy from the RNA template; env, envelope protein ensuring infectiosity of the retrovirus; env-I, env-like coding domain possessing structural features similar to env, but for which no similar function has been shown yet (a dotted box framing the env-like domain indicates that elements within the genus may or may not contain the domain); PBS, primer binding site; PPT, polypurine tract. Arrows flanking elements represent the target site duplication. The question mark linking the genera *Metavirus* and *Chromovirus* indicates that the definition of *Chromovirus* as an additional genus within the family *Metaviridae* has not been included in the official classification, with the result that many chromoviruses are still considered to be metaviruses.

coding sequences, and SINEs (short interspersed nuclear elements), small noncoding elements of a few hundred base pairs that exploit the transposition machinery of LINEs to ensure their amplification. LTR retrotransposons are by far the most abundant transposable elements in plant genomes, while LINEs appears somewhat less represented, in contrast to mammalian genomes. SINEs are also abundant in plant genomes, although their small size prevents them from playing a large structural role.

The continuous discovery of new structural variants of these major categories has made it necessary to revise and refine previous classifications. Retrotransposons have been included in a recent classification proposed for all reverse-transcribing elements, and based on viral nomenclature with type species forms defined for some genera (Table 1). All retroelements have been defined as belonging to class *Retroelementopsida*, presently divided in two orders, order *Retrovirales* that encompasses retroviruses, pararetroviruses, and LTR

Table 1 Classification of retroelements

	Type	A few examples in Viridiplantae ^a
Order Retrovirales		
Suborder Orthoretrovirineae		
Family Retroviridae (retrovirus)		Not yet
Suborder Pararetrovirineae (pararetrovirus)		
Family Hepadnaviridae		Not yet
Family Caulimoviridae		CaMV, BSV, integrated EPRVs (banana BSV; petunia PVCV, tobacco TVCV, <i>Nicotiana</i> NtoEPRV, and Ns EPRV)
Suborder Retrotransposineae (LTR retrotransposons)		
Family Pseudoviridae (Ty1/copia retrotransposons)		
Genus Pseudovirus	Ty1	Ta1 (<i>Arabidopsis</i> X1329), Tnt1 (tobacco X13777), Tst1 (potato X52387), Tto1 (tobacco D83003), WIS2 (wheat X63184), BARE1 (barley Z17327), Hopscotch (maize U12626), Tto1 (tobacco D83003), Tos17 (rice D85876), RIRE1 (rice D85597), Art1 (<i>Arabidopsis</i> Y08010), Retrofit (rice U72726), Melmoth (kale Y12321), Tgmr (soybean U96748), Stonor (maize AF082134), Panzee (pigeon pea AJ000893), Tpv2 (bean AJ005762), LERE1 (tomato AF275345), Retrolyc1 (<i>S. peruvianum</i> AF228701), AtRE1 (<i>Arabidopsis</i> AB021265), TLC1 (<i>S. chilense</i> AF279585), Toto1 (tomato AF220602), Angela (wheat DQ666286)
Genus Hemivirus	Copia	Osser (<i>Volvox</i> X69552)
Genus Sirevirus	SIRE1	SIRE1 (soybean AY205608), ToRTL1 (tomato U68072), Endovir (<i>Arabidopsis</i> AY016208) Opie-2 (maize U68408), PREM2 (maize U41000), Osr7 (rice AP002538), Osr8 (rice AC021891)
Family Metaviridae (Ty3/gypsy retrotransposons)		
Genus Errantivirus	gypsy	Not yet
Genus Metavirus	Ty3	Athila (<i>Arabidopsis</i> X81801), Cyclops (pea AJ000640), RIRE8 (rice AB014740), RIRE2 (rice AB030283), BAGY2 (barley AJ279072), Cinfu1 (maize AF049110), Grande1 (maize X97604), Piggy1 (pea AY299398), Ogre (pea AY299398), Diaspora (soybean AF095730) Genus <i>Chromovirus</i> ? del1 (lilium X13886), IFG7 (pine AJ004945), Reina (maize U69258), RIRE3 (rice AB014738), RIRE7 (rice AB033235), Galadriel (tomato AF119040), tekay (maize AF448416), Beetle1 (beet AJ539424)
Genus Semotivirus	BEL	Not yet
Genus ?	DIRS	Not yet
Unclassified		LARDs: Sukkula (barley AY054378), Squiq (rice AY355293), Spip (rice AY355292), Dasheng (rice) TRIMs: (potato AJ276865), Katydid (<i>Arabidopsis</i>), mini-Toto1 (tomato X58273)
Order Retrales		
Suborder Retroposineae (non-LTR retrotransposons)		
	L1	Cin4 (maize Y00086), del2 (lilium Z17425), Isabelle (maize AF326781), Karma (rice AB081316), Bali1A (rapeseed AF525305)
	Alu	TS (tobacco D17453), S1 (rapeseed L76840), Au (<i>Aegilops</i> AB046134)
Suborder Retronineae (bacterial retrons)		

^aElements have been classified according to year of publication or sequence submission to Genbank databases. Note that in several cases, only partial sequences are available. Extensive data on various plant elements can be found at: Repbase, a database of repetitive DNA elements of all organisms, the TIGR Plant Repeat Database and the Triticeae-specific TREP database. Retroelements were classified according to Hull R (2001) Classifying reverse transcribing elements: A proposal and challenge to the ICTV. *Archives of Virology* 146: 2255–2261; and Boeke JD, Eickbush T, Sandmeyer SB, and Voytas DF (2004) *Pseudoviridae/Metaviridae* In: Fauquet CM, Mayo MA, Maniloff J, Desselberger U, and Ball LA (eds.) *Virus Taxonomy: Eighth Report of the International Committee on Taxonomy of Viruses*, pp. 397–420. San Diego, CA: Elsevier Academic Press.

retrotransposons, and order *Retrales* that contains non-LTR retrotransposons and bacterial retrons. While order *Retrales* has not been further organized at the present time, order *Retrovirales* has been divided in several suborders, families, and genera.

Suborder *Orthoretrovirinae* contains the family *Retroviridae*, or true retroviruses, of which no example is known in plants at the present time.

Suborder *Pararetroviridae* contains two families of pararetroviruses, one of which (*Caulimoviridae*) is represented in plants. Pararetroviruses represent sensibly different lineages of retroelements, and are thought to derive from preexisting viruses having acquired a reverse transcription function, presumably from retrotransposons of the family *Metaviridae*. Many plant genomes also contain vertically transmitted integrated endogenous pararetroviral sequences (EPRVs), which represent integrated derivatives of pararetroviruses, although the infectious counterpart has not always been characterized. Plant pararetroviruses are not discussed here.

Fig. 2 The amplification cycle of LTR retrotransposons. Transcription begins in the 5' LTR and ends in the 3' LTR, and produces both the RNA template used for reverse transcription and mRNAs translated into proteins. The gag protein binds to the RNA template and forms a cytoplasmic virus-like particle (VLP). Together with the RNA template, VLPs encapsulate the RT that will produce the double-stranded DNA copy, and the integrase (int) involved in transfer of the linear DNA copy to the nucleus and its insertion in the genome.

Suborder *Retrotransposineae* contains LTR retrotransposons, and has been divided in family *Pseudoviridae* (Ty1/*copia* retrotransposons) and family *Metaviridae* (Ty3/*gypsy* retrotransposons), based on the organization of the pol domain.

The Life Cycle of LTR Retrotransposons

High Similarities with Intracellular Steps of the Retroviral Cycle

LTR retrotransposons represent by far the most abundant plant retrotransposons. They share striking similarities with animal retroviruses, both in their structure (Fig. 1) and in their replication cycle (Fig. 2). Like integrated retroviral forms (termed proviruses), LTR retrotransposons are terminated by two LTR sequences. As the reverse transcription process generates two identical LTRs, with mutations accumulating subsequently, the rate of divergences between LTRs of a given copy is often used as a molecular clock to date its insertion. The gag and pol coding domains are found between the LTRs. Other typical features include short sequences known as PBS (primer binding site) and PPT (polypurine tract). The PBS is found immediately downstream the 5' LTR, and is involved in priming of the (–)-DNA strand synthesis during reverse transcription. It is generally complementary to the 3' end of a tRNA recruited for the priming of DNA synthesis (tRNA^{met} for most *Pseudoviridae*, more variable for *Metaviridae*). The PPT is a short AG-rich sequence found immediately upstream to the 3' LTR, and involved in the priming of the (+)-DNA strand synthesis. Inserted copies are typically bounded by short direct repeat of the target host site, generated upon insertion, and usually 5 bp long for plant LTR retrotransposons.

Transcription begins in the 5' LTR, ends in the 3' LTR, and produces both the RNA template used for reverse transcription and the mRNA(s) that will be translated into proteins, after cleavage of the gag-pol polyprotein by the protease (prot) function. The gag protein binds to the RNA template and forms a cytoplasmic virus-like particle (VLP) analogous to the retroviral virion core. Together with the RNA template, VLPs encapsulate the RT that will produce the double-stranded DNA copy, and the integrase (int) that will be involved in transfer of the linear DNA copy to the nucleus and its insertion in the genome. This amplification cycle includes multiple steps of control, with transcription being absolutely crucial for retrotransposition. As a consequence, the mode of amplification of a particular element will be conditioned by its transcriptional regulation.

The amplification cycle of LTR retrotransposons is thus closely related to the intracellular steps of the retroviral cycle, with strong similarities in the reverse transcription and integration processes, as well as similar involvement of a cytoplasmic encapsulated intermediate. It has to be noticed that the amplification of non-LTR retrotransposons is sensibly different, with reverse transcription occurring at the integration site. The reality of the retroviral-type cycle of LTR retrotransposons has been demonstrated in yeast, but not yet in plants. However, VLPs have been detected for the barley BARE1 element. In addition, it has been demonstrated very recently that plant elements of the genus *Sirevirus* (see below) encode unusually large Gag domains extended in their C-terminus, and that this Gag extension binds to LC8/LC6 dynein proteins. Although the biological significance of this interaction remains to be determined, it is very similar to the binding of some human retroviruses' Gag protein to LC8 proteins to

ensure intracellular movement of virion cores along microtubules. Such observations reinforce the strong similarities between the life cycle of retroviruses and LTR retrotransposons.

The major difference between retroviruses and LTR retrotransposons resides in the infectious potentialities of the former, mediated by the *env* function that allows them to produce extracellular virions and infect host receptor cells. *Bona fide* retrotransposons, on the other hand, are not infectious and their amplification cycle is exclusively intracellular. However, we shall see later that this assumption should be treated with care and that the delimitation between retroviruses and retrotransposons is increasingly fuzzy, possibly even in plants.

It is now considered as certain that retroviruses are derivatives of some LTR retrotransposon *Metaviridae* lineages. LTR retrotransposons are themselves derived, with LINE-like ancestors, from the assembly of various modules together with an RT-like function derived from ancestral cellular functions used for the transition of genetic information from RNA to DNA at the dawn of life. Retroviruses have evolved from LTR retrotransposons through transduction of *env* domains ensuring their ability to exit the cell. Although the process can be reversed (e.g., with vertebrate endogenous retroviruses having lost their *env* functionality and reversed to a restricted intracellular life cycle), retroviruses can be seen as the ultimate evolutionary step in freeing of cellular genetic information outside of the cell, and they basically represent LTR retrotransposons that have succeeded in life. It is not clear whether this process has occurred only once during the evolution of *Retroviridae*; however, it is now increasingly clear that a number of their LTR retrotransposons' left-behind cousins have repeatedly attempted to join them in acquiring an extracellular life and that some of them have truly succeeded, albeit not yet in plants.

Evolution as Quasispecies-Like Populations

Other similarities of retrotransposons with retroviral characteristics include their high level of sequence variability. This has been best illustrated for elements related to the tobacco Tnt1 element, which are found in many species of the family Solanaceae, and evolve via a high variability of the LTR region carrying regulatory features (U3 region). Species of the genus *Nicotiana* contain Tnt1 elements that are classified into several groups (termed subfamilies) which are closely related, except in their U3 regions that differ strongly. Members of each subfamily are detected within each species, and their U3 divergence thus predates the *Nicotiana* radiation. However, the respective proportions of each subfamily differ in each species, indicating that each host species has preferentially amplified specific subfamilies. Similar evolutionary patterns have been detected in other Solanaceae species, such as tomato, pepper, or aubergine, which contain elements closely related to *Nicotiana* elements, except in the U3 region, and which can also be further subdivided in subfamilies based on the nature of the U3 region only. Interestingly, the different tobacco Tnt1 subfamilies are each expressed in response to different stimuli, within the same host genome. The very ancient Tnt1 element has thus evolved in Solanaceae a large range of highly related progeny populations that have gained new regulatory sequences and new expression patterns.

This strategy is highly similar to the evolutionary patterns of RNA viruses and retroviruses, generating populations of closely related but different genomes referred to as quasispecies. This variability has been attributed to the high-error-prone process of reverse transcription, due the lack of proofreading repair activity of RNA polymerases and reverse transcriptases. This allows viral populations to evolve very rapidly when environmental conditions change and endow retroviruses with high adaptative capacity. Thus, LTR retrotransposons similarly evolve continuums of closely related sequences, which can be defined as quasispecies-like. This evolutionary pattern allows them to vary their amplification conditions, as regulatory controls in the U3 will determine the conditions in which the element will be transcribed and amplified. The preferential amplification of specific subfamilies in each host species suggests that optimal patterns of amplification may have been selected and maintained in each host genome, possibly depending on its own evolutionary, reproductive, and environmental history.

The Different Genera of LTR Retrotransposons

The Family *Pseudoviridae* (Ty1/*copia* Retrotransposons)

Pseudoviridae are differentiated from all other LTR retrotransposons and from retroviruses by an unusual organization of the pol domain, with the *int* domain placed before the RT domain (Fig. 1). This confirms that the different LTR retrotransposon families have evolved by independent acquisition of modular functions. Historically, Ty1/*copia* retrotransposons have been the first LTR retrotransposons characterized in higher plants, and the best-known plant LTR retrotransposons belong to this family, including the tiny handful of elements for which mobility has been demonstrated. *Pseudoviridae* have been classified in the genera *Pseudovirus* (type species Ty1 of yeast), *Hemivirus* (type species *copia* of *Drosophila*), and the recent genus *Sirevirus* (type species, SIRE1 of soybean).

Pseudoviruses and hemiviruses differ by the fact that the former use a full tRNA^{met}i to prime synthesis of the (–)-DNA strand, while the latter use a half tRNA^{met}i. So far, no hemivirus has been referenced in plants, and all LTR retrotransposons usually – and incorrectly – referred to as *copia*-type retrotransposons in fact classify in the genus *Pseudovirus*. Sireviruses have so far been identified only in plants. They are phylogenetically well separated from the two other genera, and display some very interesting characteristics. In particular, several members of the genus have acquired additional ORFs carrying additional functions that present some

similarities to the env domain of retroviruses, such as a transmembrane domain (TMD). This is, for instance, the case with SIRE1, ToRTL1, and Endovir (Table 1). A number of other elements classified as sireviruses, such as Opie-2, PREM-2, Osr7, or Osr8 (Table 1), do not carry additional ORFs with typical env-like features. However, all of them carry a significant amount of noncoding DNA after the end of the pol domain, from a few hundred base pairs to over 1 kbp, while members of the genera *Pseudovirus* and *Hemivirus*, such as Tnt1, Ty1, or *copia*, separate the pol domain from the 3' LTR by a few dozen nucleotides or less. This suggests that the env-less sireviruses may also have contained similar additional ORFs that have decayed over evolutionary times.

The Family *Metaviridae* (Ty3/gypsy Retrotransposons)

The family *Metaviridae* is characterized by an organization of the pol domain identical to that of retroviruses, with the int protein encoded at the end of pol, after the RT domain (Fig. 1). Metaviruses appear to be basal to both retroviruses and pseudoviruses, and the family *Metaviridae* therefore encompasses a large variety of members, whose classification is probably not at its final stage yet. Although metaviruses have been characterized in plants more recently than pseudoviruses, they have been found to be more abundant in several plant genomes.

The family *Metaviridae* comprises the genera *Errantivirus* (type species *gypsy* of drosophila), *Metavirus* (type species Ty3 of yeast), and *Semotivirus* (type species BEL of drosophila) (Table 1). To these three genera are often added the DIRS retrotransposons, originally described from *Dictyostelium discoideum*, that show differences with other metavirus elements. DIRS do not carry typical LTRs, that is, direct repeats in the same orientation, and do not encode an int. Instead, they are bounded by inverted long repeats and integration in the host genome is ensured by a tyrosine-recombinase. In spite of these differences, they are more related to metaviruses, both in terms of RT sequence and organization of the pol domain, with the tyrosine-recombinase placed downstream to the RT domain. They could represent chimerical elements having acquired an RT domain from some metaviruses, and are placed by several authors as a putative additional genus (still unnamed) in this family. No DIRS, semotivirus, or errantivirus has yet been characterized in plants, with the totality of so-called *gypsy*-like retrotransposons of plants classified in the genus *Metavirus* (Table 1).

Errantiviruses are grouped together on the basis of the presence of an additional env-like domain, which ensures a real envelope function for the two infectious *gypsy* and ZAM elements of drosophila. *Gypsy* and ZAM are the first examples of true retroviruses outside of the vertebrate subphylum. However, their phylogenies place them quite apart from retroviruses, and they are more closely related to other LTR retrotransposons of the family *Metaviridae*. They do presumably represent recent progresses of LTR retrotransposons toward an extracellular life cycle.

The separation of errantiviruses and metaviruses has been interpreted by many authors as based on the lack of an env or env-like domain in metaviruses. However, the situation is more complex. Many plant elements presently classified in the genus *metavirus* indeed do not encode for additional ORFs after the pol domain (such as del1, IFG7, Reina, RIRE3, RIRE7, Galadriel, tekay, and Beetle-1; Table 1). In contrast to env-less sireviruses mentioned above, these elements do not show significant stretches of additional sequences between the pol domain and the 3' LTR (only a few dozens at the most, often very few), indicating that they may never have contained any additional ORF. However, a large number of plant elements presently classified in the genus *Metavirus* do contain an additional ORF with typical env-like features (such as Athila, Cyclops, RIRE8, RIRE2, BAGY2, Cinfu1, Grande1, Piggy1, or Ogre; Table 1). The two groups of elements cluster separately in most phylogenetic studies, indicating that they could be considered as two different genera of the family *Metaviridae*. An additional genus, *Chromovirus*, has recently been proposed within the family *Metaviridae*, based on the presence of a chromodomain in the integrase. However, it has not been included in the current official classification. Interestingly, all plant metaviruses devoid of additional coding domains seem to be chromoviruses. It is therefore likely that the classification of *Metaviridae* will be reconsidered in future, to separate the two groups of metaviruses and recognize the existence of the chromodomain. Interestingly, the soybean Diaspora element is devoid of any additional DNA between pol and the 3' LTR; however it clusters with env-containing elements, suggesting that its original env-like domain has been deleted. Therefore, the presence/absence of an env-like domain would not be a relevant criterion in the redefinition of genera within the family *Metaviridae*.

Unclassified LTR Retrotransposons

A number of LTR retrotransposons have recently been discovered that cannot be classified into any of the above genera due to their lack of coding sequences. The TRIMs (terminal repeat retrotransposons in miniature) consist of small LTRs framing a short central domain of noncoding sequences, while the LARDs (large retrotransposon derivatives) are larger defective derivatives that contain a large internal domain without significant similarities to retrotransposon coding domains. Both TRIMs and LARDs share many of the structural characteristics of LTR retrotransposons, such as RT priming sites PBS and PPT, and are highly amplified, suggesting efficient transactivation by functional retrotransposons. For several LARDs, sequence identities have been found with LTRs of canonical LTR retrotransposons (e.g., Dasheng with RIRE2, Squip with RIRE8, Spip with RIRE3), suggesting that they have been derived from these elements, and may eventually be classified together. Similarly, some TRIM-like small elements are derived from canonical LTR retrotransposons, such as the tomato mini-Toto1 element, derived from the Toto1 pseudovirus. In addition, a number of intermediate situations are frequently found, such as TRIM derivatives containing larger additional unknown DNA, a

possible intermediate situation between TRIMs and LARDs. The existence of TRIMs and LARDs and various intermediates indicates that plant genomes contain a large range of retrotransposons with structural features much more diverse and complex than previously thought. As long as the features required in *cis* for amplification are conserved (e.g., LTRs, PBS, and PPT, as well as a few internal sequences involved in packaging), and as long as the LTR promoter remains transcriptionally active to ensure the production of an RNA template, these defective or atypical elements can be amplified to high levels using the structural and enzymatic retroviral functions provided by their original functional parent, or possibly by other related LTR retrotransposons.

Env-Like Functions in Plants?

Although plant retrotransposons with additional ORFs of the *env* type have been detected, the potential role of such a function in infectivity remains very hypothetical in plants. Retroviral *env* glycoproteins carry a number of typical structures, such as a TMD mediating formation of infectious virions and a host receptor-binding domain, mediating targeting of host receptor cells. No significant homology to any retroviral *env* gene has been shown for any plant element; however, such identification is highly unlikely due to the intrinsic high variability shown by animal retroviral *env* proteins. As the definition of *env*-like functions in plant retrotransposons is mostly based on the presence of TMDs, the issue of the naming of these additional ORFs has been hotly debated. TMDs can also be found in various proteins, and the *env* denomination has a specific meaning related to anchoring of the protein in the membrane envelope of extracellular virion particles and to recognition of receptors on target cells to ensure viral infection after membrane fusion. Quite likely, such mechanisms are rarely used by plant viruses for host-to-host transmission, due to the cell wall barrier. Plant retrotransposons carrying additional ORFs related to functions used by most plant viruses to ensure host-to-host transmission, for example, via vector insects, have not yet been found. However, examples of enveloped viruses do exist in plants, and retrotransposon-encoded *env*-like proteins could be involved in anchoring of VLPs to cellular membranes, playing a role in cell-to-cell transmission via plasmodesmata and possibly in transmission by insects.

Furthermore, conservation of *env*-like domains has been observed between elements from different plant genera within both the *Metaviridae* and the *Pseudoviridae* (SIRE1 of soybean and Endovir of *Arabidopsis*). In addition, conserved splice acceptor sequences are detected 5' of *env*-like domains of several plant metaviruses, and production of an *env*-like spliced subgenomic RNA has been demonstrated for the barley BAGY-2 element, a mechanism similar to those used by retroviruses to ensure production of the *env* protein. In contrast, sireviruses such as SIRE1 use stop codon suppression to express *env*-like protein. The existence of such specific expression mechanisms strongly suggests that *env*-like domains are not mere incidental transduction of cellular functions, as shown for the maize Bs1 element, and that acquisition of additional coding domains with TMDs, whether in a quest or not for extracellular life, may play an important role in the plant LTR retrotransposon life cycle. In the search of a better definition, and in spite of lack of evidence for any retroviral *env*-type function, it has been proposed to maintain the *env* denomination due to its vernacular long-term use: for example, the nucleocapsid protein used to build up the VLP core particle is commonly termed *gag* in all retrotransposons, by analogy to the *gag* 'group-specific antigen' region of retroviruses, although such functional denomination does not make sense in plants.

A striking observation is that LTR retrotransposons generally have been very efficient in acquiring *env*-like domains, and have done so many times. For instance, additional ORFs with *env*-like features have been observed both for Ty1/*copia* and Ty3/*gypsy* retrotransposons, suggesting that they have been acquired independently during evolution. In addition, the *Metaviridae* contain clear examples of acquisition of *env* function from different sources, for example, from baculoviruses for *gypsy* of *Drosophila*, and from phleboviruses and herpesviruses for the semotiviruses Cer of *Caenorhabditis elegans* and Tas of *Ascaris lumbricoide*s, respectively. This indicates that LTR retrotransposons have repeatedly been able to hijack viral functions leading to extracellular autonomy, and there is no conceivable reason for plants to be an exception.

The Nomenclature Issue

Rules for naming individual elements also continue to be hotly debated. Earlier retrotransposons have been named according to authors' personal fancies (e.g., Athila, Cyclops, Opie, Ogre) or based on the plant species they were isolated from, but following no defined rule (e.g., Tnt1 for Transposon of Nicotiana Tabacum, BARE-1 for Barley Retrotransposon, WIS-2 for Wheat Insertion Sequence). An official nomenclature has recently been proposed for all retroelements, with three letters used for the species, up to three (exceptionally four) for the element and 'V' for virus. In this nomenclature, the yeast Ty1 and *Drosophila copia* elements have been renamed SceTy1V and DmeCopV, respectively, and Tnt1 and BARE1 have been renamed NtaTnt1V and HvuBV, respectively. However, this nomenclature has so far not been implemented by the plant scientific community, most likely because it does not solve the major problem arising from the presence of highly related elements in different plant species or genera, which is a general rule in plants.

In addition, most transposable element populations, and especially retrotransposons, are generally composed of populations of closely related sequences. Defining whether a particular copy is related to an already known element, or is different, is thus often a difficult task. A consensus position has been to consider that copies that show above 75% identity over most of their length (not taking into account deletions or insertions of unrelated material) are variants of the same element. However, many elements have been discovered and named independently. For instance, the wheat WIS2 and Angela elements are quite similar to the barley BARE1 element, with internal nucleotide sequences 75–80% identical between BARE1 and WIS2 and over

80% identical between BARE1 and Angela. Similarly, *Solanum* subsection *Lycopersicon* counterparts of the tobacco Tnt1 element have been named Retrolyc1 (first identified in *S. peruvianum*) and TLC1 (identified in *S. chilense*), although Retrolyc1 and Tnt1 nucleotide sequences are over 85% identical and TLC1 and Retrolyc1 are 93% identical. This highlights the difficulties inherent to a nomenclature based on host species names.

A proposition was made to replace species-based names by first names, a trend that seems to be developing at present, at least in the plant field. More specifically, it has been proposed that female first names should be used for retroelements and male first names for class II DNA transposons, although this particular proposal is not really implemented. Such type of nomenclature should alleviate the problem of the presence of related elements in different hosts, provided authors make sure their favorite first name has not been used yet. Attempts to unify the nomenclature (as well as the general classification) of transposable elements of Triticeae are currently coordinated by Dr. Thomas Wicker, who curates the TREP database for Triticeae repeats. This should lead to the redefinition of consensus guidelines that could be fruitfully followed by the entire scientific community for transposable elements of all plant genera.

Glossary

Helper component Virus-encoded nonstructural protein required for vector transmission of a virus.

Hemolymph Physiological fluid that circulates in the body cavity, or hemocoel, of arthropods in direct contact with their inner organs.

Horizontal transmission Transmission of a pathogen from one host to another within the same generation, as opposed to vertical transmission.

Phytoviruses Viruses infecting plants.

Piercing-sucking insects Insects adapted to sap or blood feeding, with the mouthparts in form of long chitin stylets

able to pierce and penetrate tissues and cells, and allow ingestion of their content.

Protist A unicellular eukaryotic organism.

Readthrough protein A protein expressed by two open reading frames separated by a stop codon that is bypassed during translation.

Vector Mobile organism acquiring a pathogen on an infected host and inoculating it in a healthy one.

Vertical transmission Transmission of a pathogen from the parent(s) to the offspring, usually through the germline.

Introduction

Plant-infecting viruses, here referred to as phytoviruses, are known since the last two decades of the 19th century. To date, over 900 species of phytoviruses have been described and their number is steadily increasing as a result of latest virological technologies. Unlike animal viruses, phytoviruses infect immobile hosts; moreover, they must cross the plant cuticula and the cell wall in order to infect living plant cells. The majority of phytoviruses have evolved a close relationship with mobile organisms, called 'vectors', which help them in their plant-to-plant propagation; this biological phenomenon is coined 'horizontal transmission'. However, some very stable viruses, such as tobamoviruses, are able to infect plants by leaf contact, or by wounds, and require no vector. Many viruses are transmissible through seed and/or pollen, and the majority can be transferred through vegetative multiplication; these routes are referred to as 'vertical transmission'. Many virus species can use both horizontal and vertical transmissions. Finally, for many viruses (e.g., in genera *Velarivirus*, *Foveavirus*, or *Hordeivirus*), the natural vector, if any, remains unknown. The present article aims at summarizing the current knowledge on the various strategies used for vector transmission of plant viruses.

Plant Virus Vectors

The vast majority of vector organisms belong to phytophagous insect taxa, mainly sap feeding members of the order Hemiptera (aphids, leaf- and planthoppers, whiteflies, coccoids). Several chewing insects in the order Coleoptera also are phytovirus vectors. Other important vectors belong to phytophagous Eriophyid and Tenuipalpid mites, to root-ectoparasitic Longidorid and Trichodorid nematodes, and to soil-dwelling plant-infecting Chytrid fungi and Plasmidio-phorid protists.

The transmission process includes several successive steps. 'Acquisition' refers to the uptake of virions while the vector feeds on an infected plant, whereas 'inoculation' occurs during a subsequent feeding on another plant. 'Latency' is the time lapse between virus acquisition and time when a viruliferous (i.e., virus bearing) vector becomes infective (i.e., able to inoculate the virus). 'Retention' time refers to the time period during which the vector remains infective. These criteria served to define the typology of the strategies involved, i.e., the transmission modes as described below.

Transmission of Plant Viruses by Insects

History of the Typology of the Transmission Modes

Vector transmission of a plant virus was first demonstrated in Japan in 1893 for the leafhopper-transmitted Rice dwarf virus (*Phytoreovirus*, *Reoviridae*). Interestingly, this discovery occurred shortly after that of insects as vectors of animal viruses. Pioneer researchers soon noticed that all virus–vector associations do not follow the same pattern, due to the specific biology of each of the three partners, i.e., plant, virus, and the vector. The typology of these ‘transmission modes’ was then defined for aphid vectors; however, it applies quite well to other vectors with a piercing-sucking apparatus, but not to beetles, equipped with biting-chewing mouthparts.

The first typology, proposed in 1939, was based on the optimal times for acquisition and inoculation and defined the ‘non-persistent’ (seconds to minutes) and the ‘persistent’ (hours to days) modes. This typology was completed in 1956 with the semi-persistent mode, with intermediary features (i.e., minutes to hours). In 1962, the second typology coined the terms circulative and stylet-borne viruses, according to whether the infectivity, and therefore the virus, is maintained or lost through molting (trans-stadial passage) and to whether the virus is detected or not in the insect hemolymph. In practice, circulative corresponds to persistent, and stylet-borne to non-persistent; however, the semi-persistent mode does not fit in this typology. In 1977, it was proposed to unify these classifications on the basis of the retention site of the virions. Thus, in the non-circulative (or externally-borne) mode, the virions are retained at the cuticular lining of stylets and/or foregut, without being transported across any epithelium, and therefore lost during molt; this includes the semipersistent mode, also named ‘foregut-borne’ according to the retention site. In the ‘circulative’ (or internally-borne) mode, the virions are internalized across the gut epithelium into the hemolymph, and from whence across the salivary gland epithelium, the circulation within the hemolymph occurring as virions. Circulative viruses are further classified as propagative or non-propagative, according to their ability to replicate or not in the vector’s organs. Furthermore, a few propagative circulative viruses are capable of a mother-to-progeny transovarial transmission.

The correspondence between feeding behavior of aphids and other hemipteran vectors, and transmission modes is well established. Aphid feeding behavior is characterized by two kinds of stylet insertion into plants. They first proceed to one or usually several brief probes (i.e., within seconds) in epidermal and mesophyll cells, during which cell content is sampled and tasted (host selection behavior) and saliva is expelled into these cells; after this phase the aphid may settle or leave the plant. If it settles, the stylets continue a deeper path into plant tissues, mainly intercellularly, to finally reach the phloem vessels, where the sap ingestion starts. Non-circulative viruses are acquired and inoculated during short probes in epidermal cells or phloem cells, in respectively non- and semi-persistent modes, whereas circulative viruses are generally acquired and inoculated during ingestion from, and salivation into phloem sieve elements. The feeding behavior of other hemipteran vectors differs somewhat from that of aphids. For example, coccoids (scale insects) make no epidermal probes, therefore transmit viruses in the semipersistent mode only. Moreover, the stylet pathway of whiteflies to the phloem is mainly intercellular, whereas that of leafhoppers, with less flexible stylets, pierce straight through mesophyll cells on hosts and non-hosts. For all hemipterans, patterns of feeding behavior vary according to host plant suitability. Many hemipterans can also ingest xylem sap, though this behavior is irrelevant to virus transmission, as xylem-located viruses are unknown.

Circulative Transmission

Circulative Non-Propagative Transmission

This strategy is very specific of phytoviruses, as it has ever been reported for the transmission of neither arthropod-transmitted animal virus (arboviruses), nor non-viral plant pathogens. The best studied pathosystems following this mode are aphids–luteovirids, leafhoppers–mastreviruses, and whiteflies–begomoviruses. Other pathosystems using this mode include aphids–nanovirids and –capulaviruses, and probably many of those involving fungus and protist vectors.

Case of Aphid-Transmitted Luteovirids

These viruses of the family *Luteoviridae*, that are causal agents of several economically important diseases in arable and vegetable crops worldwide, share the property of being phloem-restricted in their host-plants and transmitted by aphids (family *Aphididae*) during phloem feeding (Fig. 1(A)). The route of virions inside the vector has been extensively studied using cellular and molecular biology approaches. The widely accepted model is as follows. Virions are acquired into the vector along with ingested phloem sap. Then, in compatible aphid species–virus species combinations, the particles are retained at putative receptors borne by the luminal side of gut epithelium, then invaginated into gut cells and released at the basal side of these cells (‘transcytosis’) into the hemolymph. From there they diffuse, probably passively, until they reach accessory salivary glands, whose cells transport them by transcytosis from basal to apical side into the saliva (Fig. 2). They can then be inoculated during salivation into the phloem tissue of a new host. No virus particle has ever been observed in any other organ than the gut or the accessory salivary glands, nor has any viral replication ever been reported.

During transcytosis in epithelial cell of the gut and the salivary glands, virions observed using microscopy are always seen inside membranous vesicles, either alone, or grouped in clusters or tubular arrays, suggesting that the particles follow intracellular trafficking routes. In the gut, the transcytosis occurs at either the midgut, the hindgut, or both, depending on the aphid and virus species concerned. The gut barrier seems less specific than the salivary one, since viral particles are detected in the hemolymph of some non-vector species. Specificity is thought to rely on viral ligands that interact with receptors borne on the plasmalemma of

traversed cells of the gut then the salivary gland. Luteovirids have two structural proteins: the major coat protein and a minor readthrough protein composed of the coat protein at the N-terminus followed by the readthrough domain which is extended outside the particle and indispensable for the interaction with putative receptors. Recently, alanyl aminopeptidase N and ephrin receptor proteins have been shown to act as a virion receptor at the gut level, whereas other proteins are suspected to do so. During virion diffusion in the hemolymph, the readthrough protein of at least some species interacts with a chaperone protein (homolog to *Escherichia coli* GroEL) secreted by endosymbiotic bacteria; this interaction is believed to protect the particle from degradation and/or assist its transfer to the salivary glands.

Case of Leafhopper-Transmitted Mastreviruses

Unlike luteovirids, mastreviruses (*Geminiviridae*) infect mesophyll cells and are transmitted by mesophyll- and phloem-feeding leafhoppers (*Cicadellidae*) (Fig. 1(D)). Acquired virions mainly accumulate in the epithelia of the filter chamber and of the midgut, though without replication, from whence they reach the salivary glands. Unlike luteovirids, the gut provides the main selective barrier, as a non-vector can become infective upon microinjection of virions into its hemolymph, as well as upon a simple puncture of the gut wall with a needle. A probing time of less than a minute may be enough for the vector to acquire the virus, indicating that acquisition occurs in the mesophyll while puncturing cells. Conversely, inoculation, requiring longer times, occurs in phloem. Virion entry into the gut cells, mainly at the filter chamber and the anterior part of the midgut, is thought to use lipid-raft-mediated endocytosis, and the viral capsid protein is thought to bear the transmission determinants.

In the same family, the genera *Curtovirus* and *Topocuvirus* are also transmitted according to the circulative non-propagative mode, by respectively leafhoppers and treehoppers (*Membracidae*) (Fig. 1(F)). A treehopper has been reported as a vector of a *Grabovirus* member, with a still undetermined transmission mode. Finally, the recently defined genus *Capulavirus* is transmitted by aphids.

Case of Whitefly-Transmitted Begomoviruses

The genus *Begomovirus* is the genus with the largest number of species in the family *Geminiviridae*, with over 400 species described, mainly in the tropics and subtropics where they cause severe diseases to crops. The vector of all these species is exclusively the whitefly *Bemisia tabaci* (*Aleyrodidae*) (Fig. 1(B)). However, *B. tabaci* now appears as a vast complex of biotypes and 'cryptic' species, with a great invasive potential worldwide; moreover, this complexity is associated to a wide viral genetic diversity and a strong proneness to viral recombination.

Like all geminivirids, begomoviruses are reported to follow the circulative non-propagative transmission mode. However, a propagative and a transovarial transmission of Tomato yellow leaf curl virus (TYLCV) DNA by *B. tabaci* have been reported, though this

DNA is probably not infective. Moreover, the report of a venereal transmission of a specific TYLCV isolate in certain *B. tabaci* biotypes/species adds a further originality, unique among arthropod-transmitted phytoviruses. Globally, the begomoviruses–whiteflies interaction and its efficiency appear complex and diverse, possibly linked to a co-evolution between vector species or subspecies and a great diversity of viruses. Immuno-microscopic studies on several begomovirus species revealed para-crystalline structures, thought to be virions, in the filter chamber and salivary glands of the vector. Like for luteovirids, the participation of an endosymbiont-secreted chaperone protein during virion diffusion in the whitefly's hemolymph has been shown. The coat protein of begomoviruses, whose sequence is only slightly variable, determines the transmission specificity and its N-terminus is required for receptor-mediated endocytosis in the gut and salivary glands. Whitefly proteins, such as cyclophilin B, are known to be involved in TYLCV transmission.

Circulative Propagative Transmission

While circulative propagative mode is almost the general rule for arthropod-transmitted animal viruses (arboviruses), this strategy is also well known for many phytoviruses, such as the genera *Cytorhabdovirus* and *Nucleorhabdovirus* (*Rhabdoviridae*) (transmitted by leaf-, planthoppers, or aphids), *Fijivirus*, *Oryzavirus* (*Reoviridae*) and *Tenuivirus* (*Phenuiviridae*) (planthoppers), *Marafivirus* (*Tymoviridae*) and *Phytoreovirus* (*Reoviridae*) (leafhoppers), and *Tospovirus* (*Tospoviridae*) (thrips) (Fig. 1(G)). In these cases, virions infect gut cells, are then released into the hemolymph and infect various tissues and organs, including salivary glands. Rhabdoviruses infect the central nervous system, from whence they spread to other organs. The infection of the vector is very similar to the infection of an insect by an entomopathogenic virus, and the vector can therefore also be seen as a virus host, even though such vectors are usually much less impacted by the infection in terms of survival and fecundity. Remarkably, propagative phytoviruses belong (apart from marafiviruses) to families comprising also animal-infecting viruses, and the question of whether they may have evolved from insect viruses has been raised.

Non-Circulative Transmission

The non-circulative transmission is specific to phytoviruses, for which it is the most frequent case (> 50% of viruses), and unknown for vertebrate arboviruses. The virions are adsorbed at the luminal side of cuticula-lined tissues, either stylet food canal or/and foregut, without being internalized, and are therefore also called 'externally-borne'. This accounts for the loss of infectivity of the vector during molting and the shorter periods needed for efficient acquisition and inoculation (Table 2). As mentioned above, classical authors defined (1) the non-persistent mode, where the virions are acquired and inoculated from epidermal and mesophyll cells retained at the stylet level, and (2) the semi-persistent mode, where virions are acquired and inoculated from deeper cells, even in phloem, and/or retained at the foregut level (Fig. 2). However, it is sometimes uneasy to verify these features experimentally and this often vague distinction is less used today. Two hypotheses, though not mutually exclusive, have been put forward to explain the inoculation phase in this transmission mode. On one hand, the ingestion–egestion hypothesis states that the retained virions are regurgitated by the vector with the sampled plant sap during probing and feeding. On the other hand, the ingestion–salivation hypothesis, which is favored in many cases, postulates that the salivation into plant tissues is responsible to detach the retained virions and inoculate them into the host; this implies that, in the case of aphids at least, the retention site lies in the distal part of the stylets where the food and the salivary canals merge together.

Table 2 Characteristics of the different modes of vector transmission of plant viruses

Viruses	Non-circulative		Circulative	Circulative propagative
Mode	Non-persistent	Semi-persistent	Persistent non-propagative	Persistent propagative
Acquisition time	Seconds to minutes	Minutes to hours	Hours to days	Hours to days
Acquisition and inoculation sites	Epidermis	Phloem	Phloem	Phloem
Latency time	None	None	Hours to days	Days
Retention time	Minutes to hours	Hours to days	Several days	Life long
Inoculation time	Seconds to minutes	Minutes to hours	Hours to days	Hours to days
Passage through molt	No	No	Yes	Yes
Replication in vector	No	No	No	Yes
Transovarial passage	No	No	No	Possible for certain viruses
Vector specificity	Large	Medium	Narrow	Narrow

Fig. 2 Schematic representations of plant virus transmission mechanisms. Retention sites for each virus are indicated by a red star adjacent to the labeled area. C-P-Prop: circulative-persistent propagative viruses; C-P-NProp: circulative-persistent non-propagative viruses; NC-SPer: non-circulative semipersistent viruses; NC-NPer: non-circulative nonpersistent viruses. With the permission of Mauck et al. (2018). Evolutionary determinants of host and vector manipulation by plant viruses. *Advances in Virus Research* 101, 189–250.

Modern authors characterize the non-circulative mode according to the retention strategy of virus particles in the vector. In the 'capsid strategy' the virion is directly linked to cuticular sites in the vector, whereas the 'helper strategy' requires one or two extra-capsid peptides building a 'molecular bridge' between cuticular sites and virions. For both strategies, the existence of virus receptors in the vector, explaining the virus-vector specificity, has been postulated and in a few cases demonstrated. Remarkably, a helper factor has also been shown to be required in two circulative viruses, Faba bean necrotic stunt virus (FBNSV, *Nanovirus*, *Nanoviridae*) for its transfer within the aphid's hemocoel, and Rice stripe virus (RSV, *Tenuivirus*, *Phenuiviridae*) for its endocytosis into gut cells.

Capsid Strategy

Case of Aphid-Transmitted Cucumoviruses

This strategy is illustrated by the interaction between cucumoviruses and aphid vectors. The type-member Cucumber mosaic virus (CMV, *Cucumovirus*, *Bromoviridae*) is easily transmitted by aphids fed on purified virions through a stretched Parafilm™ membrane. This clearly demonstrates that virions alone are transmissible, without need for any other compound, indicating that the virion structure bears the determinant required for attachment to the cuticula. The viral retention site is likely in the stylet alimentary and/or common canals. Moreover, the three RNAs and the coat protein can be separated *in vitro*, then reassembled; thus, exchanging the components of transmissible and non-transmissible isolates confirmed the implication of the sole coat protein in transmission. Sequence modifications in this protein have been reported to modify vector specificity. Moreover, the vector-less Tobacco mosaic virus (*Tobamovirus*, *Virgaviridae*) can be aphid-transmitted when its RNA molecule is encapsidated within the capsid of a cucumovirus.

The same strategy operates in the aphid transmission of alfamoviruses and carlaviruses, as well as probably for whitefly-transmitted criniviruses; however, very few is known so far for other closterovirids.

Helper Strategy

Case of Aphid-Transmitted Potyviruses

This strategy was first described for members of the genus *Potyvirus* (*Potyviridae*). In this species-rich genus, most species are aphid-transmitted, many of them are also transmissible mechanically and some by seed. In terms of acquisition, retention, and inoculation times, potyviruses are transmitted similarly to cucumoviruses. However, purified potyvirus particles are not transmissible by aphids fed through a Parafilm™ membrane, albeit they are mechanically transmitted, showing that vector transmission requires an additional factor which is lost during purification process. Subsequent experiments proved that this factor is a virus-encoded nonstructural peptide, called helper factor or helper component (HC), released in infected cells and mediating the attachment of virions to cuticular sites during acquisition. For an efficient transmission, the HC must be taken up by the vector before or during virus acquisition, but not after. Comparison of transmissible and non-transmissible isolates or species, and mutagenesis and microscopy experiments revealed the role of the peptidic motifs, borne by the coat protein and the HC, in building a 'molecular bridge' between virion, HC and stylet cuticula. The HC is commonly designated as 'HCPro' in literature, since it also has a protease function. The precise retention site of the HC-virion complex in the vector's stylets likely comprises one or more cuticular protein(s).

Trans-complementation is another feature of the helper strategy of potyviruses. The HC of a potyvirus species can interact with the capsid of a related species acquired on the same plant or another one, due to sequence homologies, and thus assist its transmission; thus, this common phenomenon advantages the population genetics and evolution of potyvirus species.

Case of Aphid-Transmitted Caulimoviruses

Caulimoviruses (*Caulimoviridae*) are transmitted by aphids according to a particular helper strategy, that is best studied for Cauliflower mosaic virus (CaMV). Like for potyviruses, purified CaMV particles are not transmissible by artificially-fed aphids, indicating the requirement of an additional factor, later demonstrated to be the nonstructural transmission helper protein P2 expressed from the open reading frame (ORF) II of viral DNA. Moreover, a second helper peptide, the product P3 expressed from the ORF III and associated to the viral capsid, was proven indispensable in the transmission process. During cell sap ingestion, virus receptor(s) harbored on the stylets' inner cuticula retain either the complete P2-P3-virion complex simultaneously, or sequentially with P2 binding first to the stylets, followed by subsequent attachment of the P3-virion complex. In infected plant cells, CaMV virions accumulate and concentrate in specific inclusions called virus factories, whereas P2 and P3 accumulate in separate inclusions named transmission bodies. When the aphid stylets enter such cells, the transmission bodies are instantly (≤ 5 s) disrupted, and the freed P2 relocates to the cellular microtubules. Simultaneously, the virus factories release virions that join P2 on the microtubules and form transmissible virions that can be acquired efficiently by the vector. This remarkable phenomenon, coined 'transmission activation', is reversible after the stylet withdrawal. A similar reaction, i.e., vector-induced formation of transmissible virions, has recently been described for *Turnip mosaic virus*, a potyvirus, whose transmission also relies on a helper strategy.

Microscopy studies demonstrated that CaMV virions are retained at the tip of the aphid's stylet bundle, i.e., the common duct where the food and salivary canals converge, and more precisely at a particular part in the inner side of the maxillary stylets called acrostyle. Among cuticular proteins embedded in this chitinous organ, two proteins called stylin-01 and stylin-02, largely conserved among aphid species, have recently been shown to interact with either P2 or the transmissible complex P2-P3-virion, and are thus good candidate receptors for CaMV and possibly other aphid-transmitted non-circulative phytoviruses.

Transmission by Beetles

Vectors of plant viruses are known in phytophagous beetles within the Chrysomelid and Coccinellid families (Fig. 1(H)), and for members of the genera *Bromovirus* (Bromoviridae), *Comovirus* (Secoviridae), *Machlomovirus* (Tombusviridae), *Sobemovirus* (Solemoviridae), and *Tymovirus* (Tymoviridae). These viruses share isometric, stable and also mechanically transmissible particles. Virions are rapidly acquired when the vector's biting-chewing mouthparts damage plant tissues. The interaction, still poorly described, is likely ingestion-regurgitation and specific. Phytophagous beetles are devoid of salivary glands and coat their mandibles with an RNase-rich food regurgitate. The viruses transmitted display a certain resistance to RNases that may account for their vector specificity, and they are thought to translocate rapidly to unwounded cells and/or vascular tissues. In some cases, virions are detectable in the insect hemolymph within seconds, though whether this feature refers to a circulative mode or not is unknown. Some vectors can efficiently infect a plant after 'drinking' a purified virion suspension, indicating that the mere virion is required for transmission.

Transmission by Non-Insect Vectors

The transmission of several plant viruses relies on non-insect vectors (Table 1), such as mites, nematodes, and 'fungus-like' organisms (i.e., true fungi and protists).

Transmission by Mites

Two families of mites (*Acari*), *Eriophyidae* (gall mites), and *Tenuipalpidae* (false spider mites, flat mites), contain vectors of members of several virus genera (Table 1, Fig. 3(A)). However, these minute vectors have been less studied than insects, and the underlying mechanisms are poorly known, and only in some cases. For feeding, phytophagous mites empty plant epidermal cells, using a short stylet bundle. For *Brevipalpus* spp. (*Tenuipalpidae*) and *Citrus leprosis virus* (*Cilevirus*, *Kitaviridae*), virions were detected in midgut cells. Virions of the eriophyid (*Aceria tosichella*)-transmitted Wheat streak mosaic virus (WSMV, *Tritimovirus*, *Potyviridae*) were also detected in hemolymph and salivary glands. Whereas the transmission mode was long considered as non-circulative and semi-persistent, the observations mentioned above rather suggest a circulative (propagative?) interaction, but experimental proofs are lacking so far. Considering that tritimoviruses belong to the same family as aphid-transmitted potyviruses and possess an HCPro homolog ORF, experiments showed that HCPro of WSMV bears motifs required for transmissibility, even though the transmission modes (non-circulative for potyviruses) likely differ substantially between the two genera.

Transmission by Nematodes

Members of *Nepovirus* and *Cheravirus* in the family Secoviridae, and of *Tobravirus* (*Virgaviridae*) are transmitted by, respectively, longidorid and trichodorid nematodes. These nematodes feed on root cells using stylet-like organs called odontostyle and onchiostyle, respectively. The mode of transmission is described to be non-circulative, as virions are mainly adsorbed at the inner lining of the esophagus, at still unknown receptors. Despite the loss of virions during molting, *Xiphinema* spp. longidorids (Fig. 3(B)) harboring Grapevine fanleaf virus (GFLV, *Nepovirus*, Secoviridae) can remain viruliferous after at least 4 years rest in soil; thus, these slow-moving vectors provide the virus with a travel in time, rather than in space. The specific transmission of GFLV and probably other nepoviruses requires the sole capsid protein (capsid strategy), whereas that of tobraviruses needs one or two non-structural proteins (helper strategy). The viral determinants of GFLV are located around a canyon on the capsid surface and account for its vector specificity.

Transmission by Fungi and Protists

These soil-dwelling unicellular organisms, either chytrids (zoosporic Fungi or plasmidiophorid protists (*Cercozoa*) (Figs. 3(C) and (D)), have flagellate forms, called zoospores, that can enter the cytoplasm of root cells and from there colonize the plant. While doing so, these species may inoculate viruses of several genera (Table 1). Several mechanisms seemingly exist. The best documented associations are the chytrids *Olpidium* spp. transmitting tombusvirids and ophioviruses, and the plasmidiophorids *Polymyxa* spp. vectors of benyviruses and furoviruses. In the first association, during zoospore formation in infected host plants, virions bind to the zoospore external coat using fungal glycoproteins and specific regions in the capsid protein (homologous to non-circulative capsid strategy), leading to a swelling of virions. They are then released into the newly infested host cell upon cell wall digestion and fungal penetration. In the case of the protists *Polymyxa* spp. (Fig. 3(C)), the virions, or at least viral RNA-protein complexes, are endocytosed in the zoospore, presumably without replication (homologous to circulative non-propagative mode) and then inoculated into root cells with the zoospore cytoplasm. A 32 kDa viral protein was shown to be required for the transmission of a benyvirus by *Polymyxa* sp. Precise mechanisms of acquisition and inoculation are poorly known.

Host and Vector ‘Manipulation’ by Plant Viruses

Plant virus infection can drastically alter host’s phenotype, including size, color, volatiles emission, primary and secondary metabolites composition. Historically, most studies have focused on exploring the effects of viruses on plants from an agronomic point of view, such as impacts on crop yield or quality. In recent years, it has been highlighted that virus-induced changes in plant physiology may also influence host–vector interactions and, thereby, the probability of virus transmission. Given that this crucial step of transmission obligately depends on vectors for many plant viruses, it has been proposed that vector-borne viruses evolved adaptive traits that induce host phenotypes, and effects on vectors that promote their own spread. Since then, numerous studies showed that virus infection in host plants modifies vector behavior, such as orientation and settling preferences, but also reproduction and survival, in ways that are generally conducive to transmission. These effects fall into the category of putative ‘indirect manipulations’, because, in these cases, the viruses modify the behavior and/or performance of their insect vector through phenotypic alterations of the shared host. Another category of effects, qualified as ‘direct’, corresponds in changes within the viruliferous vector’s orientation and feeding preferences.

In the early 1950s, it was reported for the first time a positive effect of plant infection on the fitness of an aphid vector. Thereafter, indirect effects of plant viruses on vectors, linked to induced volatiles and to changes in leaf attractiveness and suitability for the vector, have been reported with aphid vectors, and were shown to vary according to the transmission mode of the virus. Over the last two decades, these observations were substantially confirmed and documented by many published studies with aphids and other insect vectors (whiteflies, leafhoppers, thrips, etc.). Indeed, vector-borne viruses can be classified in different categories based on their associations with the host plant and the vector ([Table 1](#)). Some viruses are restricted to the phloem tissue of their host plant, virions are thus only acquired and inoculated by vectors achieving sustained phloem sap ingestion (i.e., during hours). In contrast, viruses that are not restricted to the phloem are acquired and inoculated most efficiently during brief epidermal or mesophyll intracellular probes and are generally retained within the vector only for seconds or minutes. In this case, if the vector initiates ingestion of phloem sap prior dispersal, virus particles might be lost, and viral transmission impeded. Consequently, short probing followed by rapid dispersal is the most-conducive vector behavior for non-phloem restricted virus transmission.

From this classification, it was predicted that viruses sharing the same transmission modes – and thus, benefiting from a similar sequence of attraction, vector probing, feeding, and dispersal behavior – should exhibit convergent indirect host-mediated effects on vectors. Indeed, most phloem-restricted viruses improve the nutritive quality of the host plant for vectors (i.e., improved survival and/or fecundity), which is expected in turn to lead to crowding and subsequent dispersal of viruliferous vectors. These viruses also increase the palatability of the infected host plant compared to healthy ones, which results in improved vector feeding behavior and retention, facilitating virion acquisition from the phloem tissue. For the non-phloem restricted viruses, infections often reduce plant quality for vectors, and tend to reduce the retention of vectors on infected plants, thus potentially promoting

the rapid dispersion of viruliferous vectors to healthy plants. Regardless of the type of virus, the vectors are preferentially attracted by the visual and volatile cues of infected plants over healthy plants, which is expected to promote virus spread.

Only a few studies have documented cases of direct effects of plant viruses on vector behavior and, for the moment, the mechanisms are poorly characterized. Phloem-restricted viruses with persistent-circulative transmission mode need to perform a route from the gut to the salivary glands of their vector before they can be inoculated into a new host. These intimate associations offer strong opportunities for direct interactions of viruses on the physiology of their vector. For this kind of virus, vector dispersal is favored only after sufficient virions have been acquired by the insect to become infective. Therefore, it is predicted that these viruses may have evolved mechanisms to encourage dispersal following sustained phloem sap ingestion on infected hosts, and to discourage viruliferous vectors from visiting infected hosts; these changes in vector preference are named 'conditional vector preferences'. This hypothesis was verified on aphids carrying two luteovirids, settling preferentially on uninfected plants, while non-viruliferous aphids preferred the infected plant. The same effect was observed with aphids having acquired virions from an artificial medium (thus overcoming any potential indirect plant-mediated effect). Some examples have also documented changes in viruliferous vectors feeding behavior, such as alteration of phases related to virus transmission (i.e., salivation, phloem sap intake, sustained ingestion of phloem sap), most of which are expected to enhance the probability of virus transmission.

Future Prospects

From a mechanistic point of view, basic information on the virus-vector interaction process is increasingly documented in several cases, but is lacking in many other cases. Further studies in various transmission modes will provide a better understanding of the complex virus-vector-plant interactions, including the viral 'manipulation' of the two other partners favoring disease spread, and the localization and identification of vector receptors used by the virus for its transmission. Novel knowledge is based on ongoing progress in high-throughput data analysis and microscopic technologies.

From an evolutionary point of view, the vector provides an obvious bottleneck for the virus, since only some genome variants encapsidated in transmissible virions will be transferred into a new host plant. This issue has started to be documented but requires more information to fully understand its implications.

From an agricultural point of view, vector-borne viruses represent a burden for most crops worldwide. Since virus-infected plants remain incurable, phyto-protection against viruses mainly relies on (1) use of resistant varieties, provided resistant genes are available, although resistance-breaking viral strains are susceptible to be selected, and (2) insecticide, or acaricide and nematicide, treatments directed against the vector, which have potential environmental drawbacks and can also lead to the selection of resistant vector populations. In case of perennial crops or seed-transmitted viruses, using virus-free material is also important, even though it does not prevent further contamination. Deeper knowledge of the transmission process and the viral epidemiology is expected to generate new strategies to protect plants from viruses using vector-targeted, and more environment-friendly and integrated practices. This includes the use of molecular and/or behavioral disruption of the virus-vector-plant interaction, and the adaptation of crop management to climate change.

Glossary

Antiviral immunity Is a group of mechanisms that protect cells from virus infection. They target viral proteins or nucleic acids.

Antiviral gene silencing Is the downregulation of viral RNA accumulation. It targets viral RNA for degradation or translational repression. Additionally, in DNA viruses, it prevents transcription.

Gene silencing Is a sequence-specific gene inactivation system mediated by small interfering RNAs (siRNA). It downregulates RNA accumulation without affecting DNA sequence. It is also known as RNA interference.

Pathogenicity determinants Are viral components, usually proteins, that promote virus infection in cells and cause developmental defects in infected organisms.

Post-transcriptional gene silencing Is the degradation or translational repression of mRNA. It targets both cellular and viral RNA.

Small interfering RNAs (siRNAs) Are double-strand RNAs that measure 21–24 nt in length. siRNAs are the specificity determinant of gene silencing and program argonaute proteins for specific degradation of RNA with sequence complementarity to the siRNA.

Suppressors of gene silencing Are proteins encoded by viruses that interfere with gene silencing. Their activity prevents degradation of viral RNA, enhance transcription of viral RNA, and alters silencing of cellular genes. These effects are in part responsible for developmental defects in virus infected organisms.

Transcriptional gene silencing Prevent inhibits transcription from chromosomes, plasmids or viral DNA mini chromosomes. It is directed by siRNAs guiding enzymatic DNA methylation.

Virus-induced gene silencing Virus infection induces silencing of cellular genes with sequence similarity to viral RNA.

Introduction

Gene silencing is a sequence-specific gene inactivation system mediated by small interfering RNAs (siRNA) that measure 21–24 nt. Gene silencing downregulates RNA accumulation without affecting DNA sequence and is also known as RNA interference. Gene silencing regulates gene expression at the transcriptional or post-transcriptional levels. Transcriptional gene silencing is directed by siRNAs guiding enzymatic DNA methylation and inhibits transcription from chromosomes, plasmids or viral DNA mini chromosomes. Post-transcriptional gene silencing is the nucleolytic cleavage and degradation or translational repression of mRNA (**Fig. 1**). The pathway and biological roles of gene silencing are conserved in eukaryotes.

Gene silencing regulates gene expression in a temporal and tissue-specific manner to control development, response to stress, and to preserve genome integrity. Additionally, in plants, nematodes, and insects, gene silencing is an essential component of antiviral immunity. In these organisms, plant viruses are inducers and suppressors of gene silencing. Our mechanistic understanding of gene silencing and virus-encoded gene silencing suppressors is derived mainly from the study of plant viruses. Accordingly, this article is focused on suppressors of gene silencing encoded by plant viruses.

Viruses use RNA to replicate, express their genes, or both. The RNA might be perceived by the cell and activates antiviral defense, including gene silencing and mRNA decay. DNA viruses are targeted by both transcriptional and post-transcriptional gene silencing. RNA viruses, viroids and satellite RNAs are targeted by post-transcriptional gene silencing. To overcome gene silencing and promote susceptibility, viruses encode suppressors of gene silencing that are essential for viruses to replicate and spread. Virus-encoded gene silencing suppressors interfere with antiviral defense, and have been identified in plant viruses, insect viruses, fungal viruses and in some viruses infecting humans. However, the antiviral role of gene silencing in mammals is only beginning to be elucidated.

In plant-virus interactions, the establishment of infection is determined by the balance between antiviral gene silencing versus virus evasion or suppression of antiviral defense. Endogenous and antiviral gene silencing have conserved and overlapping pathways. Accordingly, virus-encoded silencing suppressors affect both endogenous and antiviral gene silencing and their effects are in part responsible for symptom development in infected plants.

Antiviral Gene Silencing Pathway

Antiviral gene silencing is non-cell autonomous, initiates at the single cell level and spreads cell-to-cell and long distance through plasmodesmata and the plant vascular system. The pathway consists of four parts: Initiation, targeting, amplification, and systemic spread (**Fig. 2**). Upon initial detection, Dicer-like (DCL) proteins process viral dsRNA into virus-derived siRNA that associate with

Fig. 1 Flow of genetic information and gene silencing in plants. RNA-induced silencing complexes are formed between effector proteins and small interfering RNAs (siRNAs) derived from non-coding transcripts. Gene silencing is a block in the flow of genetic information by preventing transcription (transcriptional gene silencing) or by inducing degradation or translational repression of protein-coding RNAs (post-transcriptional gene silencing). In addition to endogenous long non-coding RNAs and siRNAs, virus-infected plants accumulate virus-induced siRNAs and virus-derived siRNAs, which enter the RNA-induced silencing complex and program degradation of host or viral mRNA. Gene silencing is essential for normal development and antiviral immunity. It targets viruses at the transcriptional or post-transcriptional level. Adapted from Garcia-Ruiz, H., Ruiz, M.T.G., Peralta, S.M.G., Gabriel, C.B.M., El-Mounadi, K., 2016. Mechanisms, applications, and perspectives of antiviral RNA silencing in plants. *Mexican Journal of Phytopathology* 34, 286–307.

argonaute (AGO) proteins to form RNA-induced silencing complexes (RISC) that target viral mRNA, and potentially host mRNAs, for endonucleolytic cleavage or translational repression. Initial recognition of viral RNA is necessary but not sufficient to restrict plant virus infection. Restriction of infection requires silencing amplification by cellular RNA-dependent RNA polymerases (RDRs). After moving out of the infected cell, in recipient cells the silencing response is amplified. Cellular RDRs synthesize new viral dsRNA that is the substrate for the formation of secondary virus-derived siRNAs that move systemically ahead of the virus to establish an antiviral state.

DNA viruses express their genes through mRNA. Silencing is activated at the post-transcriptional level, resulting in the formation of virus-derived siRNAs that guide targeting of viral RNA. Furthermore, virus-derived siRNAs in association of AGO and RDR proteins guide methylation of viral DNA to prevent mRNA transcription (transcriptional gene silencing). Combined, the effects of both transcriptional and post-transcriptional gene silencing create an antiviral state that prevents virus replication and movement.

Small Interfering RNAs Direct Antiviral Immunity

Through their association with AGO proteins, virus-derived siRNAs are the specificity determinant guiding translational repression or cleavage of viral RNA with sequence complementarity. In a variation of the pathway targeting DNA viruses, silencing complexes formed by virus-derived siRNAs and AGO proteins direct methylation of viral DNA to prevent transcription. In both cases, the end result is the inhibition of virus replication and movement. In plant-virus interactions, several phenomena are mediated by gene silencing such as cross protection, symptom recovery, synergism, and non-host resistance.

Cross protection occurs when infection by a mild virus strain prevents subsequent infection by a second virus of the same or closely related species. siRNAs-derived from the mild virus strain direct targeting of viruses with sequence similarity. However, not all cross-protection cases are explained by gene silencing. In *Turnip crinkle virus*, and *Wheat streak mosaic virus*, suppressor infection exclusion is a form of cross protection mediated by viral proteins.

Symptom recovery has been described for several plant-virus combinations, such as *Arabidopsis thaliana* infected by *Oilseed rape mosaic virus* or *Tobacco rattle virus*. Infected plants accumulate high virus titers and develop visible symptoms. However, the upper leaves of those plants contain low virus titers and do not develop symptoms. Virus-derived siRNAs formed in the lower part of the plant move systemically to the meristem to direct viral RNA targeting and prevent virus invasion of the meristem. Leaves formed after that harbor virus-derived siRNAs that mediate virus downregulation. Interestingly, in recovered *A. thaliana* tissue, the suppressor from *Oilseed rape mosaic virus* lost its activity.

Fig. 2 Antiviral gene silencing and basic components in plants. In infected cells, viruses are recognized by dsRNA replication intermediates or self-complementary sequences in genomic RNA or mRNA. Dicer-like (DCL) proteins cut viral dsRNA to form primary virus-derived small interfering RNAs (siRNAs), that associate with argonaute (AGO) proteins and program endonucleolytic slicing and degradation or translational repression of viral RNA. Host transcripts with sequence complementarity to virus-derived siRNAs might be targeted. Slicing of viral RNA triggers amplification of antiviral RNA silencing that results in the formation of viral dsRNA by cellular RNA-dependent RNA polymerases (RDR) and processing by DCL to form secondary-virus-derived siRNAs. Silencing amplification triggers methylation of viral DNA which results in transcriptions silencing. Virus-derived siRNA move cell-to-cell and systemically to establish a state of antiviral immunity away from the initial infection site. Adapted from Garcia-Ruiz, H., Ruiz, M.T.G., Peralta, S.M.G., Gabriel, C.B.M., El-Mounadi, K., 2016. Mechanisms, applications, and perspectives of antiviral RNA silencing in plants. Mexican Journal of Phytopathology 34, 286–307.

Several mechanisms explain non-host resistance, such as the absence of pro-viral factors needed for replication or movement. However, antiviral gene silencing early in infection guided by endogenous siRNAs or virus activated siRNAs might target viral RNA to prevent the establishment of infection and plants show the phenotype of a non-host.

Viral Suppressors of Gene Silencing Promote Infection

Gene silencing is an essential component of antiviral immunity in plants, insects, and nematodes. To establish infection, viruses must protect themselves from antiviral defense responses such as RNA decay, gene silencing and protein-based

mechanism such as autophagy or ubiquitination. At least two mechanisms have been proposed to explain gene silencing: evasion and suppression. Positive-strand RNA viruses replicate in membrane bound compartments that sequester replication intermediates. Negative-strand RNA viruses and dsRNA viruses replicate in enveloped vesicles. These structures might prevent access to viral dsRNA by the gene silencing machinery. In an interesting variation of gene silencing, a non-coding region in *Cauliflower mosaic virus* produces large amounts of siRNAs that saturate the silencing machinery. This decoy role prevents targeting of viral RNA.

Mechanisms of Gene Silencing Suppression

To protect themselves from gene silencing and promote infection, most plant and some insect viruses encode silencing suppressors that inactivate gene silencing by multiple mechanisms (Table 1) discussed below.

Table 1 Representative virus-encoded gene silencing suppressors

<i>Virus</i>	<i>Suppressor</i>	<i>Silencing target</i>	<i>Other functions</i>
siRNA binding			
Potyruses	HC-Pro	siRNA monomers and dimers	Virus movement, symptom development, pathogenicity determinant
TBSV	P19	siRNA dimers	Virus movement, symptom development pathogenicity determinant
BYV	P21	siRNA dimers	Required for replication
TSWV	NSs	siRNAs	Pathogenicity determinant
WDV	Rep	siRNAs	Viral DNA replication
RGDV	PNS11	siRNAs	Pathogenicity determinant
ACMV	AC4	Single strand siRNAs	Viral synergism
Long dsRNA binding			
PoLV	P14	dsRNA and siRNAs	Symptom determinant
TCV	P38	dsRNA	Virion formation Virus movement
FHV	B2	dsRNA	NA
AGO degradation or inhibition			
CMV	2b	AGO1 AGO4	Virus movement
PVX	P25	AGO1	Virus movement
ToRSV	CP	AGO1	Virion formation
Polerovirus	P0	AGO1	Pathogenicity determinant
TCV	P38	AGO1 AGO2	Virion formation Virus movement
DCL inhibition			
RYMV	P1	DCL1 upregulation, DCL4	Pathogenesis, symptom development
TCV	P38	DCL1 upregulation, DCL4	Virion formation Virus movement
Silencing amplification inhibition			
RDV	PNS10	RDR6 downregulation	ND
TuMV PVA	VPg	RDR6 and SGS3 downregulation	RNA translation
CaMV	P6 (TAV)	DRB4 inactivation	Cell-to-cell movement, NPR1 downregulation, translational activator
RGDV	PNS12	NA	
Interference with siRNA methylation			
TMV	129K	HEN1	RNA replication
Tombusvirus	P19	siRNAs	Virus movement, symptom development
DNA methylation interference			
TYMV	P69	NA	Symptom determinant
TGMV BCTV	AL2 L2	Adenosine kinase inhibition	Pathogenesis
CaLCuV	AL2		
Activation of cellular transcription			
EACMV	AC2	Cellular transcription	Viral synergism
CaLCuV	AL2	Cellular transcription	Transcription activation
Decoy RNA			
CaMV	35S RNA translational leader	Overloading DCL	Translation, reverse transcription template

Viruses: African cassava mosaic virus (ACMV), East African cassava mosaic virus (EACMV), *Beet curly top virus* (BCTV), *Beet yellows virus* (BYV), *Cabbage leaf curl virus* (CaLCuV), *Cauliflower mosaic virus* (CaMV), *Cucumber mosaic virus* (CMV), *Flock house virus* (FHV), *Potato virus A* (PVA), *Potato virus X* (PVX), *Pothos latent virus* (PoLV), *Rice gall dwarf virus* (RGDV), *Rice dwarf phytoecovirus* (RDV), *Rice yellow mottle virus* (RYMV), *Tobacco mosaic virus* (TMV), *Tomato bushy stunt virus* (TBSV), *Tomato golden mosaic virus* (TGMV), *Tomato ringspot virus* (ToRSV), *Tomato spotted wilt virus* (TSWV), *Turnip crinkle virus* (TCV), *Turnip mosaic virus* (TuMV), *Turnip yellow mosaic virus* (TYMV), *Wheat dwarf virus* (WDV).

Small RNA Binding

Potyviral HC-Pro, tombusviral p19, and others, bind siRNAs of viral and cellular origin including microRNAs and secondary siRNAs. Binding by silencing suppressors prevents association of siRNAs with AGO proteins. Consequently, RISC complexes are not formed and viral RNA, and host mRNAs, are not targeted. As a consequence, host genes normally downregulated by siRNAs, accumulate to levels higher than normal and plants display malformation that resemble symptoms caused by virus infection.

Inhibition of siRNA Biogenesis

Several virus-encoded gene silencing suppressors interfere with the biogenesis of siRNA by at least two mechanisms: binding long dsRNA and altering homeostasis of core genetic components of the pathway (**Table 1**). Binding long dsRNA prevents access to DCL proteins and inhibits siRNA formation. Some suppressors induce degradation of cellular components needed for amplification of gene silencing, such as RDR6, SGS3 or DRB4. In both cases, the end result is a reduction in the biogenesis of virus-derived and endogenous siRNAs.

Homeostasis of Gene Silencing Components

Core components of gene silencing (DCL, AGO, RDR, and DRB proteins) are targeted for degradation by some virus-encoded gene silencing suppressors (**Table 1**). *Cucumber mosaic virus* 2b and polerovirus P0 induced degradation of AGO1. AGO1 mainly associate with microRNAs and is essential for normal plant development. AGO2 and AGO4, are also needed for plant development and are targeted for degradation by silencing suppressors.

Turnip crinkle virus P38 inhibits activity of DCL4, the first line of defense against viral RNA, and prevents biogenesis of DCL4-dependent siRNAs. Furthermore, DCL1 downregulates expression of DCL4 and DCL2, which have essential roles in siRNA biogenesis in both endogenous and antiviral gene silencing. Several viruses upregulate DCL1, consequently downregulating DCL4 and DCL2 to protect viral RNA from silencing.

Inhibition of Assembly or Activity of RNA-Induced Silencing Complexes

The catalytic components of RNA-induced silencing complexes (RISC) are binary complexes formed between AGO proteins and siRNAs. Several virus-encoded silencing suppressors inhibit assembly or activity of RISC complexes by binding siRNAs or targeting AGO proteins for degradation (**Table 1**). Interestingly, in a complementary mechanism 2b, the silencing suppressor encoded by *Cucumber mosaic virus* and related species, binds to AGO1 and prevents cleavage of target mRNA.

Inhibition of Silencing Amplification

A critical step in antiviral gene silencing is the systemic spread and amplification of silencing signals to establish a state of antiviral immunity away from the initially infected tissues (**Fig. 2**). The silencing signal consists of siRNAs, very likely in endosomes. After moving out of the initially infected cell, silencing is amplification by cellular RNA-dependent RNA polymerases (RDRs) and auxiliary proteins such as suppressor of gene silencing (SGS3) and double stranded RNA binding protein 4 (DRB4). Silencing amplification consists on the synthesis of new viral dsRNA that is processed by DCL proteins into secondary virus-derived siRNAs that move ahead of the virus to establish an antiviral state. Some virus-encoded gene silencing suppressors prevent spread or amplification of the gene silencing signal (**Table 1**). The mechanisms are dependent on siRNA sequestration, or induction of degradation of key components of secondary siRNA biogenesis, such as RDR6, SGS3 or DRB4.

Interference With DNA Methylation

Plants silence geminiviruses by methylating their mini chromosomes through transcriptional silencing. As counter-defense, some geminiviruses encode suppressors that interfere with DNA methylation (**Table 1**). AL2, encoded by *Cabbage leaf curl virus*, and L2 encoded by *Beet curly top virus*, interact with and inactivate adenosine kinase (ADK). ADK is a methyl cycle-associated enzyme required for the efficient production of S-adenosyl methionine (SAM), an essential methyltransferase co-factor. These viral suppressors interfere with methylation of both viral mini chromosomes and host chromosomes. The former promotes viral infection. The latter is associated to symptom development.

Activation of Cellular Transcription

AL2, encoded by *Cabbage leaf curl virus*, and AC2 encoded by *East African cassava mosaic virus* are a transcription factor that suppresses post-transcriptional gene silencing by upregulating plants genes that negatively regulate gene silencing: Werner exonuclease-like 1 (WEL1), and regulator of gene silencing-calmodulin-like protein (rgsCam). In the presence of WEL1 and rgsCam gene silencing is less effective, thus favoring virus infection.

Assays to Identify and Characterize Gene Silencing Suppressors

Viral suppressors of gene silencing have been identified and characterized using a standard transient assay in *Nicotiana benthamiana*. The assay consists in providing a transgene encoding green fluorescent protein (GFP) as a reporter gene. Accumulation of GFP is initially evaluated using a hand-held UV lamp. The GFP transgene is normally silenced by the plant in two days. However, when a silencing suppressor is provided, GFP expression remains active for 4–5 days. Both the GFP transgene and genes being tested are delivered using *Agrobacterium tumefaciens* carrying binary vectors. This assay measures suppression of transgene silencing in infiltrated leaves (local silencing), and *N. benthamiana* can be wild type or constitutively express a GFP transgene (16C). The 16C line was developed by Dr. David Baulcombe's group in 1998 and has been widely used to visualize local and systemic gene silencing. In 16C *N. benthamiana* plants, GFP is silenced in the infiltrated leaves and the silencing signal moves systemically. After 10–15 days of triggering local silencing, GFP silencing is evident in young leaves, as a result of systemic gene silencing. Assays using 16C *N. benthamiana* have been used to identify suppressors that interfere with movement or perception of the gene silencing signal.

In a variation of the assay, suppressor-deficient Turnip crinkle virus (TCV) tagged with GFP (TCV-GFP) is used instead of a single- or double-stranded GFP. TCV-GFP is unable to move cell-to-cell in *N. benthamiana* and is co-expressed with a gene of interest using *A. tumefaciens* carrying binary vectors. Silencing suppressors restore cell-to-cell movement to TCV-GFP and local infection foci visible to the naked eye are formed.

After initial identification in transient assays using single- or double-stranded GFP or TCV-GFP as reporter genes, silencing suppressors are further tested in a heterologous virus, most commonly *Potato virus X* (PVX). PVX expressing a heterologous silencing suppressor normally cause more severe symptoms than the wt PVX.

In a complementary approach, silencing suppressors have been expressed constitutively expressed in model plants such as *A. thaliana* or *N. benthamiana*. Examples are potyviral HC-Pro, CMV 2b, and polerovirus P0. Interestingly, plants expressing one of these silencing suppressors, display development defects that resemble AGO mutants or symptoms characteristic of virus infected plants. These observations support the model that silencing suppressors interfere with endogenous gene silencing and cause the developmental malformations perceived as symptoms in virus infected plants.

Using these assays, a large number of silencing suppressors have been identified in plant and insect viruses. Interestingly, proteins encoded by several human viruses have suppression activity in these assays. Vaccinia virus E3L and *Influenza virus* NS1 have gene silencing suppression activity. However, the biological role of this activity remains to be determined. Furthermore, *Dengue virus* proteins NS3 and NS4 are silencing suppressors. Since *Dengue virus* is transmitted by mosquitoes these proteins likely protect the virus from silencing in the mosquito.

Viral Suppressors of Gene Silencing Need Cellular Factors

Virus-encoded gene silencing suppressors are essential pathogenicity determinants necessary for viruses to interfere with gene silencing. Interestingly, some virus-encoded gene silencing suppressors interact with and need host factors to function. For example, RAV2, an ethylene-inducible transcription factor, is required for suppression of gene silencing by potyviral HC-Pro and TCV P38. In *N. benthamiana*, the calmodulin-like protein (Nbrgs-CaM) is an endogenous plant regulator of gene silencing that functions by repressing expression of RDR6. RDR6 and SGS3 participate in the biogenesis of secondary siRNAs necessary to amplify endogenous and antiviral gene-silencing signals against RNA viruses and geminiviruses. Infection of *N. benthamiana* by *Tomato yellow leaf curl China virus* and the associated β C1 DNA satellite induces expression of Nbrgs-CaM that in turn downregulates RDR6 expression, thus reducing antiviral defense mediated by gene silencing.

Evolution of Viral Suppressors of Gene Silencing

Most silencing suppressors are multifunctional and perform activities necessary for completion of the infection cycle, such as viral RNA replication, virus movement, virion formation or vector transmission (Table 1). Accordingly, virus-encoded silencing suppressors act through diverse mechanisms and are structurally diverse. Furthermore, even for suppressors with the same mechanism, their amino acid sequence is generally diverse. These features have limited the use of computational approaches to identify and characterize gene silencing suppressors and supports the model that silencing suppression has evolved multiple times, independently, through convergent evolution due to host pressure imposed through gene silencing as an antiviral mechanism.

Effect of Gene Silencing Suppressors on Plant Development

A wide range of biological processes are regulated through silencing mechanisms, including plant development, organ formation, and stress responses in eukaryotes. Thus, perturbation of silencing pathways leads to changes in host gene expression that alter normal development. This effect is, at least in part, responsible for symptom development in virus infected plants. As an example, the abaxial-adaxial leaf polarity is regulated by siRNA gradients moving between cells. AGO7 and AGO10 are expressed specifically

in the adaxial leaf primordial and in vascular tissues. AGO7 restricts activity of miR390 and directs a gradient of trans-acting small interfering RNAs from the adaxial to the abaxial side of developing leaves.

Virus-encoded silencing suppressors such as potyviral HC-Pro, orthotospoviral NSs and tombusviral P19 bind cellular miRNAs, and secondary siRNAs. Additionally, potyviral VPg induces degradation of SGS3 and RDR6. TCV P38 inactivates DCL4, while polerovirus P0 and CMV 2b induce AGO1 degradation (Table 1). Collectively, these effects prevent activity of cellular microRNAs and the biogenesis or activity of trans-acting secondary siRNAs. Normal activity of cellular miRNAs and trans-acting secondary siRNAs is essential for plant development. As a consequence of silencing suppression, host genes normally downregulated by siRNAs, accumulate to levels higher than normal and plants display malformation that resemble symptoms caused by virus infection.

Silencing Suppressors Mediate Viral Synergism

Viral synergism occurs when co-infection by two viruses results in disease with more severe symptoms than single virus infection. Most documented cases of viral synergism involve viruses in the family *Potyviridae* and depend on silencing suppressors HC-Pro or P1. Potyviral HC-Pro binds both endogenous and virus-derived siRNAs, their own and those derived from co-infecting viruses. siRNA binding by HC-Pro prevents targeting of viral RNA and results in higher accumulation of the non-potyvirus and symptoms are more severe than those of single infection. An example of economic importance is maize lethal necrosis, caused by the coinfection of Maize chlorotic mottle virus and Sugarcane mosaic virus. Maize lethal necrosis is a re-emerging disease that has reached epidemic proportion and is threatening food security in sub-Saharan Africa. In potato, co-infection by Potato virus X and Potato virus Y causes synergism. In pepper, co-infection by Cucumber mosaic virus and Pepper mottle virus causes synergism. Similarly, in papaya co-infection by Papaya mosaic and Papaya ringspot virus causes synergism. In all these cases, the non-potyvirus accumulates to higher levels in plants double infected, compared to plants single infected. Interestingly, accumulation of the potyvirus is similar in single or double-infected plants. The genetic determinant of synergism is potyviral silencing suppressor HC-Pro.

There is one documented case of synergism in DNA viruses. In cassava, a synergistic disease is caused by the co-infection of African cassava mosaic virus (ACMV) and East African cassava mosaic virus (EACMV). ACMV and EACMV encode AC4 and AC2, respectively, that suppress gene silencing by different mechanisms. Furthermore, it is the only documented case of synergism between viruses of the same genus.

Viral Suppressors in Support of Biotechnology

Several pharmaceutical products, including vaccines against human pathogens such as influenza viruses are produced in plants. The corresponding coding sequence is provided as a transgene, which often is turned off by gene silencing. In transient assays, this limitation has been resolved using virus-encoded gene silencing suppressors, which enhance gene expression and boost yield of the pharmaceutical product of interest.

Nomenclature

ABA	Absciscic acid	ORF	Open reading frame(s)
AGO	Argonaute	PDS	Phytoene desaturase
CHS	Chalcone synthase	PTGS	Post-transcriptional gene silencing
CP	coat protein or capsid protein	RdRp	RNA-dependent RNA polymerase
dsRNA	Double stranded RNA	RISC	RNA-induced silence complex
HSP90	Heat shock protein 90	RNAi	RNA interference
LIC	Ligation-independent cloning	SGN	Solanaceae genomics network
mRNA	Messenger RNA	UTR	Untranslated region
NLR	Nucleotide-binding leucine rich repeat	VIGS	Virus-induced gene silencing
NOS	Nopaline synthase	VPGD	VIGS phenomics and functional genomics database
		VPI	Vascular puncture inoculation

Glossary

Agrobacterium-mediated genetic transformation

Agrobacterium genetically transforms its host by transferring a well-defined DNA segment from its tumor-inducing (Ti) plasmid to the host-cell genome.

Agro-infiltration It is a method used in plant biology and especially lately in plant biotechnology to induce transient expression of genes in a plant, or isolated leaves from a plant, or even in cultures of plant cells, in order to produce a desired protein. In the method a *suspension* of *Agrobacterium tumefaciens* is introduced into a plant leaf by direct injection or by vacuum infiltration, where after the bacteria transfer the desired gene into the plant cells via transfer of T-DNA.

Argonaute It is a family of proteins that bind small noncoding RNAs, including miRNAs and siRNAs, and are guided to RNA targets through sequence complementarity, leading to the cleavage or translation inhibition of mRNAs, including viral RNAs.

Co-suppression phenomenon understood as post-transcriptional gene silencing, which can be triggered by introducing transgenes or a certain viruses expressing the target gene.

CRISPR-Cas Clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated proteins (Cas) is a prokaryotic adaptive immune system that can be leveraged for genetic material to be added, removed, or altered at particular locations in the plant genome, or to directly target viral DNA or RNA molecules.

Dicer It is a multidomain ribonuclease that processes double-stranded RNAs to 21-nt small interfering RNAs during RNA interference and excises microRNAs from precursor hairpins.

Forward genetics Approaches used to identify directly genes responsible for a particular phenotype of an organism (DNA).

Functional genomics The study of genes with respect to the role they play within biological processes.

Knockdown Reduction in the expression of a gene.

Knockout Complete inhibition of gene expression.

MicroRNAs These are a class of small non-coding ~21–24 nt RNAs that are involved in the regulation of gene expression at the post-transcriptional level by degrading target mRNAs, including viral RNAs, and/or inhibiting their translation.

Post-transcriptional gene silencing Silencing of an endogenous gene caused by the introduction of a homologous dsRNA, transgene or virus. In PTGS, the transcript of the silenced gene is synthesized but does not accumulate because it is rapidly degraded.

Reverse genetics Approaches used to define the function of a gene or sequence of DNA within the context of the organism (RNA, proteins).

RNA interference It is a ribonucleoprotein complex that incorporates one strand of a miRNA or a siRNA duplex for RNAi.

RNA-induced silencing complex It is a ribonucleoprotein complex that incorporates one strand of a miRNA or a siRNA duplex for RNAi.

Small interfering RNA It is a class of 20–25 nt non-coding dsRNA molecules.

Trans-acting siRNA These are siRNA that repress plant gene expression through post-transcriptional gene silencing.

Introduction

Virus-induced gene silencing (VIGS) is an effective forward and reverse genetics approach in plants. VIGS uses the antiviral defense mechanism in plants to transiently downregulate specific transcripts through a recombinant vector. The VIGS vector, which carries a partial sequence from the gene to be silenced, is introduced into the plant cell via *Agrobacterium tumefaciens*-mediated transient transformation or using in vitro-generated transcripts. Double stranded RNA (dsRNA) molecules generated during viral infection trigger the RNA interference (RNAi) pathway; leading to the degradation of messenger RNAs (mRNAs) homologous to the dsRNA and subsequent downregulation of the corresponding gene. The first VIGS vector, based on Tobacco mosaic virus (TMV), was developed in 1995. The last two decades have seen a significant increase in the number of viruses that have been adapted for VIGS to study gene function in plants. VIGS has major advantages over the labor-intensive transgenic approaches including speed, efficacy and cost. These attributes have made VIGS a versatile functional genomic tool in a wide range of plant species to unravel gene functions involved in a variety of plant biological processes.

PTGS and VIGS

The term “cross-protection” was first described in the 1920s as a phenomenon of induced resistance in a host plant against one virus or viroid strain infection if the host plant had been previously infected with another milder strain of the same virus or viroid. However, the mechanistic basis of this phenomenon was not understood. In 1990, researchers attempted to develop an enhanced purple colored petunia flower by overexpressing a pigmentation gene *chalcone synthase* (CHS). Unexpectedly, the flowers of CHS overexpressing plants were either entirely white or a mottled purple/white. This phenomenon was named “co-suppression” and considered to be an oddity of petunia. In the following few years, the same phenomenon was reported in many other plant species. The “cross-protection” and “co-suppression” phenomenon were soon understood as post-transcriptional gene silencing (PTGS), which could be triggered by introducing transgenes or using viruses as gene carrier. Around the same time, a similar phenomenon was described in the fungus *Neurospora crassa* and named as “quelling”. This phenomenon has since been observed in many organisms, including nematodes, flies, and mammals; coming to be known more widely as RNA interference (RNAi). These cross-kingdom PTGS/quelling/RNAi are evolutionary conserved and induced by dsRNA.

The term VIGS was coined in 1997 and used to describe the symptoms recovery phenomenon of plants upon viral infection. As mentioned above, viral infection activates the plant RNAi-mediated antiviral defense mechanism, PTGS. The machinery involved in PTGS targets the viral genome as an antiviral defense. This was exploited as the basis of VIGS. Now, VIGS specifically refers to the reverse genetics technique for down-regulation of target gene expression in plants by recombinant viruses which carry a partial sequence of the target gene.

PTGS is activated upon virus infection in plants. During the viral replication process, dsRNA intermediates are generated. Synthesis of dsRNA is mediated by RNA-dependent RNA polymerase (RdRp). DNA viruses employ the host RdRp for the dsRNA synthesis, while RNA viruses encode their own RdRp for the dsRNA production. Viral dsRNAs are recognized as host aberrant RNAs and cleaved by the host plant's Dicer-like ribonuclease, producing short interfering RNA (siRNA) duplex molecules which are of 21–24 nt in length. The siRNA duplex can then be recognized and unpaired by Argonaute (AGO) protein into a guide strand and a passenger strand in an ATP-dependent manner. The Passenger strand is degraded while the Guide strand is loaded into a multi-protein complex known as the RNA-induced silencing complex (RISC). The RISC complex, harboring siRNA, scans the mRNA population inside the cell and specifically targets transcripts that are complementary to siRNA, resulting in cleavage of target transcript. As a result, the mRNA level of the target gene is reduced. The silencing signal can be further amplified by plant RNA-dependent RNA polymerase 6 (RDR6) and spread systemically throughout the plant, causing systemic gene silencing.

Establishment of a VIGS System

To develop a virus vector into a more efficient VIGS tool, the selected virus should have a broad host range and should cause only mild disease symptoms. In this way, the VIGS-vector-induced silencing phenotype will not be obscured by disease symptoms. The best VIGS vectors are characterized by high silencing efficiency as well as persistent silencing phenotype. Furthermore, uniform expression of a silencing phenotype, in a tissue-independent manner, is also an important factor that should be considered when choosing a virus for VIGS vector development.

In the last two decades, many plant viruses have been used to develop VIGS vectors. Most VIGS vectors are derived from RNA viruses, with a few DNA viruses and satellites having been used as well (Table 1). For development of a VIGS vector, the viral genome is cloned under the control of a constitutive promoter such as Cauliflower mosaic virus (CaMV) 35S promoter and a terminator such as nopaline synthase (NOS) terminator in a T-DNA binary vector. The VIGS T-DNA vector, containing the target gene insert, is transferred into plants via *Agrobacterium tumefaciens*-mediated transient plant transformation system or DNA of VIGS vector could be delivered by biolistic bombardment. In addition, transcripts of T7 promoter-based VIGS vector generated by in vitro transcription could be used for rub-inoculation onto plants. Agroinfiltration is the most widely used method for VIGS because it is inexpensive and highly reproducible. Syringe infiltration is commonly used to introduce the agrobacterium into the

Table 1 List of plant viruses used as VIGS vectors for gene silencing and their experimental plant hosts

<i>Virus</i>	<i>Genus/Family</i>	<i>Host species</i>
RNA virus		
Apple latent spherical virus (ALSv)	<i>Cheravirus Secoviridae</i>	<i>Chenopodium quinoa</i> , soybean, apple and <i>Nicotiana benthamiana</i>
Bamboo mosaic virus (BaMV)	<i>Potexvirus Alphaflexiviridae</i>	<i>Brachypodium distachyon</i>
Barley stripe mosaic virus (BSMV)	<i>Hordevirus Virgaviridae</i>	Wheat, barley
Bean pod mottle virus (BPMV)	<i>Comovirus Secoviridae</i>	Soybean
Brome mosaic virus (BMV)	<i>Bromovirus Bromoviridae</i>	Maize
Cucumber mosaic virus (CMV)	<i>Cucumovirus Bromoviridae</i>	<i>Nicotiana benthamiana</i> and maize
Cymbidium mosaic virus (CymMV)	<i>Potexvirus Alphaflexiviridae</i>	Orchid
Foxtail mosaic virus (FoMV)	<i>Potexvirus Alphaflexiviridae</i>	Barley, wheat, foxtail millet, and maize
Pea early browning virus (PEBV)	<i>Tobravirus Virgaviridae</i>	<i>Medicago truncatula</i> and pea
Potato virus X (PVX)	<i>Potexvirus Alphaflexiviridae</i>	<i>Nicotiana benthamiana</i>
Tobacco rattle virus (TRV)	<i>Tobravirus Virgaviridae</i>	<i>Nicotiana benthamiana</i> , tobacco, tomato, potato, pepper, <i>Arabidopsis</i> , cotton, poppy and others
Turnip yellow mosaic virus (TYMV)	<i>Tymovirus Tymoviridae</i>	Chinese cabbage and <i>Arabidopsis</i>
DNA virus		
African cassava mosaic virus (ACMV)	<i>Begomovirus Geminiviridae</i>	Cassava
Cabbage leaf curl virus (CaLCuV)	<i>Begomovirus Geminiviridae</i>	<i>Arabidopsis</i>
Cotton leaf crumple virus (CLCrV)	<i>Begomovirus Geminiviridae</i>	Cotton
Pepper huasteco yellow vein virus (PHYVV)	<i>Begomovirus Geminiviridae</i>	Pepper
Rice tungro bacilliform virus (RTBV)	<i>Tungrovirus Caulimoviridae</i>	Rice
Tomato golden mosaic virus (TGMV)	<i>Begomovirus Geminiviridae</i>	<i>Nicotiana benthamiana</i>
Satellite virus		
Satellite Bamboo mosaic virus (satBaMV)	<i>Potexvirus^a</i>	<i>Brachypodium distachyon</i>
Tomato yellow leaf curl China betasatellite (TYLCCNV)	<i>Begomovirus^a Geminiviridae</i>	Tomato

Four week old *N. benthamiana* plants infected with TRV-*NbPDS* show photobleaching phenotype (right panel) compared to the TRV-VIGS vector (left panel) infected plant. Pictures were taken two weeks post VIGS vector inoculation.

plants. However, other delivery routes such as spraying, vacuum infiltration and agro-drench have also been used to deliver VIGS vector containing T-DNA vectors in plants.

Virus-encoded silencing suppressor genes can reduce VIGS silencing efficiency and should be removed or modified in the VIGS vector. Some non-essential genes, for example, those that are not necessary for viral replication, cell-to-cell movement and systemic movement, could be removed from the viral genome while constructing a VIGS vector. To clone a target gene fragment into a VIGS vector, an appropriate position in the viral genome should be selected in such a way that it does not interfere with viral lifecycle. In some cases, a sub-genomic promoter from a related virus has been used in a VIGS vector to drive the expression of a target gene for silencing. To clone the target gene fragment into the VIGS vector, the restriction/ligation, gateway cloning, or ligation-independent cloning (LIC) strategies have been used. The optimal gene fragment length for efficient silencing of a target gene is between 200 and 500 bp. However, gene fragments as short as 23 nt are sufficient to knockdown target gene expression. The silencing

Fig. 2 VIGS assay applied to tomato fruit. (A) Phenotype of *Nor*-silenced fruit. Vector only (pTRV2-00) and *PDS*-silenced (pTRV2-*PDS*) fruits were used as the control. (B) Flow chart of the VIGS assay for tomato fruit. To construct the pTRV2 vector, a fragment of the target gene (FTG) was inserted into the multiple cloning site (MCS). pTRV1 and pTRV2 plasmids were independently transferred to *A. tumefaciens* (GV3101). The cells in the LB cultures containing pTRV1 and pTRV2 were harvested and mixed at a ratio of 1:1 after resuspension in *Agrobacterium* infiltration buffer (AI buffer); the mixture was used to infiltrate the carpel of the tomato fruit attached to the plant at 7–10 DPA. (C) The silencing efficiency of the *Nor* gene in AC tomato fruit at the red-ripe stage (RR). CaMV 35S promoter (35S), nopaline synthase terminator (NOST), coat protein (CP). Luria-Bertani medium (LB). Asterisks indicate a significant difference as determined using Student's t-test (**, $P < 0.01$). Role of the tomato non-ripening mutation in regulating fruit quality elucidated using iTRAQ protein profile analysis PLOS ONE 11, e0164335. Available at: <https://doi.org/10.1371/journal.pone.0164335>.

efficiency varies depending on the target region selected. Therefore, multiple fragments targeting different regions of the target gene of interest should be tested. In view of this, Solanaceae Genomics Network (SGN) VIGS Tool (See Relevant Websites Section) could be used to select an optimal target gene fragment for cloning into a VIGS vector.

VIGS Vectors

Many VIGS vectors developed to-date have been used for gene silencing in dicot plants. Since *Nicotiana benthamiana* is susceptible to a wide range of plant viruses and amenable to agro-infiltration it is widely used to test the efficacy of a newly developed VIGS vector. The

(C) a, Negative control-silenced upland cotton (Zhongzhimian KV3, CLCrV-00); b, GhGsSRK-silenced Zhongzhimian KV3 plant; c, GhWRKY2-silenced Zhongzhimian KV3 plant; d, GhWRKY29-silenced Zhongzhimian KV3 plant; e, GhFLS2-silenced Zhongzhimian KV3 plant; f, Negative control-silenced upland cotton (86-1, CLCrV-00); g, GhWRKY13-silenced 86-1 plant. (D) The disease index (DI) after silencing different genes. The results are presented as mean $\pm$ standard deviation (SD) from three replicates with at least 20 plants per replicate. Black represents candidate gene silenced in Zhongzhimian KV3, and blue represents candidate gene silenced in 86-1. Asterisk represents the data point that was statistically different from wild-type and CLCrV-00 plants ($p < 0.05$) analyzed by one-way ANOVA, using the SAS 8.1. The vertical bars indicate standard Deviation. Reproduced Fig. 3 from Zhang, W., Zhang, H., Liu, K., *et al.*, 2017. Large-scale identification of *Gossypium hirsutum* genes associated with *Verticillium dahliae* by comparative transcriptomic and reverse genetics analysis. PLOS ONE 12 (8), e0181609. Available at: <https://doi.org/10.1371/journal.pone.0181609>.

Tobacco rattle virus (TRV)-VIGS vector is by far the most widely used VIGS vector due to its broad host range and high silencing efficiency in addition to its very mild disease symptoms. TRV is a bipartite, positive-strand RNA virus consisting of RNA1 and RNA2 genomes. Since the RdRp, movement protein, and 16K protein encoded by RNA1 are essential for TRV infection, the RNA1 is unmodified in the TRV-VIGS system. The cDNA corresponding to RNA1 is cloned under the control of a 35S promoter and a NOS terminator (TRV1). In RNA2, the coding region required for vector transmission has been removed and the cDNA corresponding to the remaining parts are cloned between a 35S promoter and a NOS terminator. In RNA2 vector (TRV2), a multiple cloning site, gateway cloning cassette, or ligation-independent cloning cassette has been introduced downstream of intergenic region after the coat protein (CP) open reading frame (ORF). TRV-VIGS has been used successfully for gene function studies in more than 25 plant species including a large number of plants in *Solanaceae* (Figs. 1 and 2), as well as in *Malvaceae* (Fig. 3), *Brassicaceae*, *Euphorbiaceae*, *Papaveraceae* and *Rosaceae*. In legumes, Bean pod mottle virus (BPMV) and Pea early browning virus (PEBV) have been used successfully as VIGS vectors.

Fig. 4 *PDS* and magnesium chelatase subunit H (*ChlH*) gene silencing phenotypes in barley, wheat and *B. distachyon*. (A) Barley showing phenotypes typical of suppression of *ChlH* and *PDS* by BSMV:*HvChlH* or BSMV:*HvPDS* inserts of the indicated lengths. (B) Upper panel: Wheat inoculated with BSMV:*TaChlH*₂₅₀ showing more than 90% of inoculated plants developing the chlorotic phenotype associated with suppression of the *ChlH* gene. Middle panel: *PDS* and *ChlH* gene silencing phenotypes on wheat leaves infected with BSMV:*TaChlH* and BSMV:*PDS* derivatives with different length inserts. Bottom panel: PCR amplification of transcripts from leaves shown in the middle panel. (C) *B. distachyon* leaves showing effects of *PDS* suppression after infection with BSMV:*BdPDS* inserts. In these experiments, plants were inoculated at the two-leaf stage with infected *N. benthamiana* sap harboring BSMV derivatives targeting *PDS* and *ChlH* cognate genes from each species. Leaf photographs were taken at 14 dpi, and fragment lengths from each source are indicated as subscripts above each leaf. Relative transcript levels of *PDS* and *ChlH* genes in the leaves infected with the different BSMV derivatives are shown under the leaf photographs. RNA extracted from the leaves was subjected to semi-quantitative RT-PCR amplification (28 cycles for wheat and barley, 31 cycles for *B. distachyon*) with the gene-specific oligonucleotide primers. Amplified species-specific 18S rRNA served as internal controls for each species. Reproduced Fig. 6 from Yuan, C., Li, C., Yan, L., et al. 2011. A high throughput Barley stripe mosaic virus vector for virus induced gene silencing in monocots and dicots. PLOS ONE 6, e26468. Available at: <https://doi.org/10.1371/journal.pone.0026468>.

Very few vectors have been developed for gene silencing in monocot plants (Table 1). Monocots are generally recalcitrant to agro-infiltration. As such, mechanical inoculation methods such as rub-inoculation of crude sap from infected *N. benthamiana* plants, in vitro generated VIGS vector transcripts, or vascular puncture inoculation (VPI) of in vitro transcripts or virions has been used to introduce VIGS vectors into monocots. Brome mosaic virus (BMV) and Barley stripe mosaic virus (BSMV; Fig. 4) VIGS vectors have been used to silence genes in maize, wheat and barley. Recently, Foxtail mosaic virus (FoMV)-based VIGS vector has been used to silence genes in barley, wheat, foxtail millet, and maize and Cucumber mosaic virus (CMV)-based vector has been used to silence genes in maize.

Generally, *Phytoene desaturase* (*PDS*), a gene involved in carotenoid biosynthesis, has been used as a target to test the efficacy of newly developed VIGS vectors. Since carotenoid synthesis is important for photosynthesis and photoprotection, low levels of carotenoids result in a degradation of chlorophyll. This is manifested in a visible photobleaching phenotype in *PDS* silenced plants (Fig. 1). This visible feature makes *PDS* an excellent positive control for monitoring the silencing efficiency.

VIGS Application

VIGS vectors have been used widely as a reverse and forward genetic tool to unravel the functions of genes involved in various biological processes such as disease resistance, cell death, abiotic stress, cell signaling, flower development (Fig. 5), fruit development (Fig. 2), secondary metabolite biosynthesis, and evolutionary developmental biology.

The role of Heat Shock Protein 90 (HSP90) in Rx1 nucleotide-binding leucine rich repeat (NLR) class receptor-mediated immunity was uncovered in a forward genetics by screening nearly 5000 cDNAs in TRV-VIGS vector in *N. benthamiana* plants. The role of autophagy in immunity and cell death in plants was uncovered by screening TRV-VIGS library. Similar TRV-VIGS library was used to identify the role for ribosomal proteins, RPL12 and RPL19, in non-host disease resistance against bacterial pathogens in *N. benthamiana*.

Numerous studies have used VIGS as a reverse genetics tool to study gene function in the literature. NCBI PubMed database using the term "VIGS" lists 828 publications. Majority of these publications describe using VIGS to discover gene function in various plant biological processes. By far the most application of VIGS is in the disease resistance area (168 publications in NCBI). VIGS has been used to study function of genes involved in disease resistance in various plants including *N. benthamiana*, tomato, pepper, potato, soybean, wheat, barley, maize, cotton, cassava, and other plants.

In addition to biotic interaction, VIGS has been used to study abiotic stress responses. VIGS vectors based on TRV, BSMV, BPMV, PEBV, and Tomato yellow leaf curl China virus (TYLCCNV) have been used successfully to study genes function in abiotic

Fig. 5 Virus-induced gene silencing of *Thalictrum clavatum* AGAMOUS ortholog TcAG-1 results in homeotic floral phenotypes. (A) Flower silencing phenotypes of TcAG-1, relative to controls. Ai, Untreated flower of *T. clavatum* showing sepals (se), stamens (st) and carpels (ca); Aii: strongly silenced flower in TRV2-TAG-1 treated plant, showing an array of sepals and no stamens nor carpels, all reproductive organs have been homeotically converted to sepals; Aiii: intermediate phenotype with partial conversion of organs and some normal ones; Aiv: detail of dissected organs in an untreated flower (sepal, stamen, carpel, from left to right); Av: detail of all sepaloid dissected organs from a strong TcAG-1 silencing phenotype (from the outside to the inside of the flower, left to right); Avi: detail of sample chimeric organs, arrows point to anther tissue on the edges of an internal “sepal”. Scale bar = 1 mm. (B) Gene expression by Reverse Transcriptase (RT)-PCR in TcAG-1 silenced plants compared to controls. Untreated and mock-treated (empty TRV2) plants are compared to TRV2-TAG-1 treated plants showing strong homeotic conversions (Aii, Av). RT-PCR was performed with locus-specific primers to the housekeeping gene ACTIN (loading control); to the MADS box gene TcAG-1 and to the viral transcripts TRV1/TRV2. For TRV2: larger bands result from the presence of insert, the smaller band from an empty TRV2 (mock control). Reproduced Fig. 4 from Di Stilio, V.S., Kumar, R.A., Oddone, A.M., *et al.*, 2010. Virus-induced gene silencing as a tool for comparative functional studies in *Thalictrum*. PLOS ONE 5, e12064. Available at: <https://doi.org/10.1371/journal.pone.0012064>.

stress responses including drought, highlight, iron deficiency, oxidative stress, abscisic acid (ABA) response, salt stress, osmotic stress, dehydration and nutrient deficiency in crop plants such as tomato, pepper, pea, soybean, wheat, and barley.

Many groups have also used VIGS to study genes involved in various plant developmental pathways including flower and fruit development. Genes involved in flower development has not only been studied in model plants such as *N. benthamiana* and *Arabidopsis* but also in crop plants such as tomato, petunia, soybean, and cherry. In addition, TRV-based VIGS has been used in comparative studies involving flower development genes in basal eudicots such as *Aquilegia*, *Cysticapnos vesicaria*, *Papaver somniferum* (opium poppy) and *Eschscholzia californica* (California poppy); *Gerbera hybrida*, *Phalaenopsis* orchids, and rose. TRV-based VIGS has been used successfully to uncover the role of genes involved in fruit development in tomato, pepper, peach, and strawberry.

Recently, a database describing phenotypes resulting from silencing of approximately 1300 genes in *N. benthamiana* has been developed, VIGS phenomics and functional genomics database (VPGD; See Relevant Websites Section). Since genes in *N. benthamiana*

have homologs in other *Solanaceae* plants such as tomato, potato and pepper; one could infer the function of the corresponding genes in these crop plants.

Advantages and Limitations

VIGS is an efficient forward genetic approach to identify loss-of-function phenotypes of specific genes. TRV-VIGS requires less than 2 weeks to knockdown target gene expression in *N. benthamiana* plants. However, it usually takes 3–4 months to generate transgenic *N. benthamiana* with the traditional *Agrobacterium*-mediated genetic transformation; homozygous lines require additional time. Additionally, the transformation process is labor-intensive and expensive. The VIGS could be used to silence a single gene or even multiple genes. Since VIGS has been applied in a broad range of plant species, it is possible to conduct comparative studies using homologous genes in different plant species.

Many plants are highly recalcitrant to genetic transformation. For some genes in sexually propagated plants, the mutation or antisense-mediated knockdown is lethal. In these cases, VIGS can serve as a valuable alternative for gene function studies as it eliminates the need to establish a stable genetic transformation method. Silencing of a specific gene within a multi-gene family and silencing multi-copy genes in polyploid plants is also feasible by VIGS method by choosing the targeting sequence derived from the most conserved region among gene family members. Similarly, one could use 3' untranslated region (UTR) to specifically silence a single gene within a gene family.

VIGS, like any technique, has limitations. The silencing effect of VIGS is transient. However, silencing by TRV-VIGS has been shown to last for longer time. Another limitation is that VIGS fails to completely knockdown target gene expression. In some cases this imperfect knockdown may not manifest in a phenotypic change compared to the control plants. Since the VIGS vector is essentially an infectious plant pathogen, the silencing process along with virus infection may interfere with the plant metabolism which could affect the results of some studies. Therefore, it is always important to use negative control such as VIGS vector alone (Fig. 1) without any target insert in VIGS experiments to make sure that the observed phenotype is specifically due to the knockdown of a target gene. VIGS is an ideal method for preliminary identification of function of genes due to its quick and easy features. Following preliminary identification with VIGS, the most promising candidate genes could be further validated with other approaches.

Conclusion and Prospects

VIGS is an efficient forward and reverse genetic technique that exploits the plant's PTGS mechanism. It facilitates the down-regulation of single genes or gene families. A large number of plant viruses have been engineered as VIGS tools for gene function studies in a variety of plant species. In the last 20 years, VIGS has made a significant contribution to gene function studies in various plant processes. With the availability of more plant genome sequences in the post-genomic era, the improvement of existing VIGS vectors as well as the development of new VIGS vectors for additional plant species is required for VIGS-based functional genomic studies to achieve its full potential in plants.

Glossary

Multi-vesicular bodies Organelles bound by a membrane that contain intraluminal vesicles that mediate transport between the trans-Golgi network and vacuoles.

Poly(A)-binding protein Regulatory proteins that bind to the poly(A) tail of mRNAs.

T-DNA vector Plasmid with the T-DNA (transferred DNA) sequence of the Ti plasmid of *Agrobacterium tumefaciens*, which is transferred to plant cells where it can be transiently expressed or become integrated in the plant genome.

Transgenic P12 tobacco Tobacco plants that express P1 and P2 replicase proteins from nuclear genes inserted via a T-DNA vector.

History

Alfalfa mosaic virus (AMV) was identified in 1931 as the causal agent of an economically important disease in alfalfa. Purification of AMV around 1960 showed that virus preparations contained bacilliform particles of different length. Fractionation of these particles by sucrose-gradient centrifugation revealed that the four major components each contained a specific type of RNA, termed RNAs 1, 2, 3, and 4. Initially, an analysis of the biological activity of the viral nucleoproteins and RNAs resulted in a puzzle. A mixture of the three largest viral particles was fully infectious, but a mixture of RNAs 1, 2, and 3, purified from these particles, was not. At the RNA level, RNA4 was required in the inoculum to initiate infection. In 1971, it became clear that the AMV genome consisted of RNAs 1, 2, and 3, and that a mixture of these genomic RNAs became infectious only after addition of capsid or coat protein (CP) or its sub-genomic messenger, RNA4. High-affinity binding sites for CP were identified in the AMV RNAs in 1972 and could be localized to the 3' termini of the RNAs in 1978. From 1975 onwards it became clear that, similar to AMV, the ilarviruses required the CP to initiate infection. Moreover, the CPs of AMV and the ilarviruses could bind to the 3' termini of each other's RNAs, and could be freely exchanged in the initiation of infection. Currently, AMV is the type species of the genus *Alfavirus* and is classified together with the genus *Ilarvirus* in the family *Bromoviridae*.

Taxonomy and Classification

In addition to the genera *Alfavirus* and *Ilarvirus*, the family *Bromoviridae* contains the genera *Bromovirus*, *Cucumovirus*, *Anulavirus*, and *Oleavirus*. These viruses all have three positive-sense single-stranded genomic RNAs packaged into separate particles with sub-genomic, defective, or satellite RNAs. The particles are bacilliform or spherical. AMV has been placed into a separate genus from the other viruses because of its mode of transmission (aphids, pollen, and seed), its shape (bacilliform), and its very wide host range. In addition, AMV requires CP for the initiation of infection (termed 'genome activation'), whereas other members of the family do not, except for the ilarviruses. It has been suggested that the alfamoviruses and the ilarviruses be combined into a single genus, but this has yet to be resolved. The ilarviruses differ from AMV, however, by mode of transmission (thrips/pollen) and shape (irregular spheres). Many isolates of AMV are known which are closely related serologically and by nt sequence similarity. The complete nt sequences of AMV isolate 425 (Leiden [L] and Madison [M] isolates) were the first determined; GenBank now contains 11,602 full and partial sequences of many additional strains and isolates. The genetic diversity of the sequences is generally low with agro-ecological factors affecting their distribution.

Particle Structure and Composition

Fig. 1 shows an electron micrograph of AMV. The four major classes of particles in AMV preparations are called bottom component (B), middle component (M), top component *b* (Tb), and top component *a* (Ta). B, M, and Tb are bacilliform and contain the genomic RNAs 1, 2, and 3, respectively. Ta contains two molecules of the sub-genomic RNA4 and can be subdivided into bacilliform Ta-b and spheroidal Ta-t particles. The bacilliform particles are all 19 nm wide and have lengths of 56 nm (B), 43 nm (M), 35 nm (Tb), and 30 nm (Ta-b) (**Fig. 1(A)**). The RNAs are encapsidated by a single type of CP, which in the case of strain AMV-L has a length of 220 aa (Mr 24.3 kDa). In solution, AMV CP occurs as dimers, which under appropriate conditions of pH and ionic strength form a $T=1$ icosahedral structures built from 30 dimers. This structure can be crystallized and has been studied by X-ray diffraction, cryoelectron microscopy, and image reconstruction methods (**Fig. 1(B)**). The CP was found to have the canonical eight-stranded β -barrel fold with the N- and C-terminal arms as extended chains. Dimer formation in the $T=1$ particle is based on the clamping of the C-terminal arms of the subunits.

From particle weight measurements and analysis of electron microscopic images, it was determined that the number of CP monomers in the major viral components is 60 p ($n \times 18$), n being 10 (B, 240 subunits), 7 (M, 186 subunits), 5 (Tb, 150 subunits), or 4 (Ta, 132 subunits). By gel electrophoresis, at least 13 minor components have been resolved which probably represent other n values and contain monomers of genomic RNAs, multimers of genomic RNAs or RNA4, or specific degradation products of RNA3. Although details of the arrangement of the protein monomers have not been established, electron microscopical studies indicate that the cylindrical parts of the bacilliform particles have a hexagonal surface lattice with dimers of CP associated with the twofold symmetry axes. The cylindrical portion of the particle is thought to be capped by two halves of an icosahedron by changing the axes from sixfold symmetry in the cylinder into axes of fivefold symmetry. Neutron scattering data suggested that the capsid structure of spheroidal Ta-t particles is represented by a deltahedron with 52-point group symmetry built from 120 subunits. The percentage of RNA in the particles decreases from 16.3 in B to 15.2 in Ta-b. The buoyant density in CsCl of the major components fixed with formaldehyde varies from 1.366 (Ta) to 1.372 (B) g cm^{-3} . The protein shell has an inner radius of 6.5 nm and an outside radius of 9.4 nm. The RNA is uniformly packed within the 6.5 nm radial limit, occupies about 20% of the interior volume available, and slightly penetrates the protein shell to stabilize the particles by protein–RNA interactions. The RNA is easily accessible to ribonucleases A and T1 through holes in the protein shell.

Genome Structure

The genome structure of AMV strain 425 is shown in **Fig. 2**. RNAs 1 and 2 encode the replicase proteins P1 and P2, respectively. P1 contains an N-terminal methyl-transferase-like domain and a C-terminal helicase-like domain, whereas P2 contains a polymerase-like domain. RNA3 is dicistronic and encodes the 5' proximal movement protein (MP) gene and the 3' proximal CP gene. MP and CP are both required for cell-to-cell transport of the virus. CP is translated from RNA4, which is identical in sequence to the 3' terminal 881 nt of RNA3. The length of the intercistronic region in RNA3 is 52 nt including the leader sequence of RNA4 of 36 nt. At the 5' end, all four AMV RNAs are capped. The organization of the leader sequence of RNA3 varies between strains. For strains M, S, L, and Y the length of this leader sequence is 240, 313, 345, and 391 nt, respectively. The increased length of the last three strains is due to the presence of direct repeats of 56 (S), 75 (L), or 149 (Y) nt. At their 3' termini, the viral RNAs contain a homologous sequence of 145 nt. The 3' 112 nt of this sequence may adopt two mutually exclusive conformations, one representing a strong CP binding site (CPB) and the other representing a transfer RNA-like structure (TLS) resembling the TLS of bromo- and cucumoviruses. The 112 nt CPB structure, consists of four hairpins

Fig. 2 Structure of the AMV genome. RNAs 1 and 2 are monocistronic and encode the replicase proteins P1 of ~110 kDa, and P2 of ~85 kDa. RNA3 is dicistronic and encodes a movement protein of ~34 kDa and coat protein of ~22 kDa. CP is translated from sub-genomic RNA4 (not shown). The gray squares represent the 3' terminal 112 nt of the RNAs, which can adopt either a tRNA-like structure or a structure with high affinity for CP. From: Bujarski *et al.*, 2019. Journal of General Virology 100, 1206–1207.

(designated A, B, C, and D from 3' to 5' end) flanked by tetranucleotide sequences AUGC (or a UUGC derivative). Base-pairing between a four nt sequence in the loop of the 5' proximal hairpin D and a four nt sequence in the stem of the 3' proximal hairpin A results in a pseudoknot interaction that generates the TLS structure. Structures similar to the AMV CPB and TLS conformations have been identified at the 3' termini of the RNAs of the ilarviruses. The TLS of AMV and ilarviruses cannot be charged with an aa as can the TLS of bromo- and cucumoviruses, but it can be recognized by the host enzyme that adds CCA to the 3' termini of cellular tRNAs (CTP/ATP: tRNA nucleotidyl transferase).

Interaction Between Viral RNA and Coat Protein

In vitro, the 3' untranslated region (UTR) of AMV RNAs can bind several dimers of CP. A minimal CP binding site consists of the 3'-terminal 39 nt of the RNAs with the structure 5'-AUGC-[hairpin B]-AUGC-[hairpin A]-AUGC-3'. This structure contains two overlapping binding sites for the N-terminus of the two subunits of a CP dimer. The consensus binding site in the RNA is UGC-[hairpin]-RAUGC (in which R is a purine). In addition to dimers of native CP, N-terminal peptides of CP can bind the 39 nt RNA fragment in a 2:1 ratio. The N-terminus of CP contains basic residues at positions 5, 6, 10, 13, 16, 17, 25, and 26, but only arginine-17 appears to be critical for binding of CP to RNA. This Arg residue is part of a Pro-Thr-x-Arg-Ser-x-x-Tyr (PTxRSxxY) RNA binding domain conserved among AMV and ilarvirus CPs.

A complex of the 3' terminal 39 nt RNA fragment and peptides corresponding to the N-terminal 26 aa of CP has been crystallized and its structure was solved to 3 Å resolution. Co-folding altered the structure of both peptide and RNA (**Fig. 3**). In the co-crystal, hairpins A and B are oriented at approximately right angles and each hairpin is extended by 2 bp formed between nt from adjacent AUGC sequences. If the AUGC motifs in the 39 nt fragment are numbered 1–3, starting from the 3' end of the RNA, hairpin B is extended by a duplex formed by base-pairing between the U and C residue of motif 3 and the A and G residue of motif 2. Similarly, hairpin A is extended by a duplex formed by base-pairing between the U and C residue of motif 2 and the A and G residue of motif 1. The two peptides in the co-crystal each form a helix with residues 12–26 ordered in peptide 1 and residues 9–26 ordered in peptide 2. The data has provided insight into the role of the PTxRSxxY-motif in RNA binding. *In vitro* selection of RNA fragments with high affinity for full-length AMV CP from a pool of randomized RNAs yielded fragments that maintained the unusual inter-AUGC base pairs observed in the crystal structure, but the primary sequences diverged from the wild-type RNA.

Translation of Viral RNA

Extension of the 3' end of AMV genomic RNAs with an artificial poly(A)-tail increased the basal level of infectivity of these RNAs 50-fold, compared to a 1000-fold increase caused by binding of CP to the RNAs. A role of CP in translation of viral RNAs was investigated by extension of the 3' end of a luciferase reporter RNA with the AMV 3' UTR [Luc-AMV]. CP stimulated translational efficiency of Luc-AMV 40-fold without affecting the half-life of Luc-AMV. GST-pull-down assays and Far Western blotting revealed that AMV CP specifically interacted with the eIF4G-subunit in the eIF4F initiation factor complex from wheat germ and with the eIFiso4G-subunit from the eIFiso4F complex in plants. This interaction allows the formation of a closed-loop structure for AMV RNAs similar to that formed by the interaction of poly(A) binding protein (PABP), the poly(A) tail of eukaryotic mRNAs, and the eIF4G-subunit during translation (**Fig. 4**). Therefore, AMV CP stimulated translation of viral RNAs by mimicking the PABP.

Protoplasts transfected with wild-type AMV RNA4 accumulated CP at a detectable level, although accumulation was 100-fold lower than in productively infected protoplasts. However, translation of an RNA4 mutant, R17A, which encodes a CP with

Fig. 3 Proposed structure of the entire 3' end of AMV RNA. A. Diagram of the 3' untranslated region (UTR) with color-coded U-C-hairpin-A-G CP-binding sites. B. End-on view of the simulated 3' UTR. C. View of the 3' UTR along its length. RNA is colored green; peptide is colored yellow. From Guogas, L.M., Filman, D.J., Hogle, J.M., Gehrke, L., 2004. Cofolding organizes alfalfa mosaic virus RNA and coat protein for replication. *Science* 306, 2108–2111.

Fig. 4 Model for the role of coat protein in translation of AMV RNAs. Translation of cellular mRNAs is strongly enhanced by the formation of a closed-loop structure by interactions of the poly(A) binding protein (PABP) with the 3' poly(A) tail and with the eIF4G subunit of the eIF4F complex of initiation factors bound to the 5' cap structure (upper panel). AMV coat protein (CP) enhances translational efficiency of viral RNAs 40-fold by binding to the CP binding site (CPB) at the 3' end of the viral RNAs. The finding that CP also interacts with eIF4G indicates that CP mimics the function of PABP in formation of the closed-loop structure (lower panel).

arginine-17 replaced by alanine that is unable to bind to the 3' end of AMV RNAs, was below the detection level. Translation of mutant R17A could be rescued to wild-type levels by expression in *trans* of a CP that was functional in RNA binding. Also, translation of this mutant was rescued to wild-type levels by replacing its 3' UTR by the 3' UTR of brome mosaic virus (BMV) RNA4. BMV is the type species of the genus *Bromovirus* in the family *Bromoviridae* and its 3' UTR stimulates translation independently of CP, possibly by the binding of host factors.

Replication of Viral RNA

AMV replication complexes are associated with vacuolar membranes. Replicase protein P1 recruits P2 to multivesicular bodies, also called prevacuolar compartments. P1 and P2 localize to the tonoplast in the presence of full-length AMV RNA suggesting that functional replicase complexes assemble on multivesicular bodies (MVBs) then traffic to the tonoplast. Template-dependent replicase preparations were purified from infected normal and transgenic plants that constitutively express the replicase proteins. The purified replicase preparations, which specifically accept exogenous AMV RNA as template, were used to study viral minus-strand and plus-strand RNA synthesis *in vitro*. The identification in 1978 of high-affinity binding sites for CP at the 3' termini of AMV RNAs led to the hypothesis that binding of CP was required to permit initiation of minus-strand RNA synthesis. However, all experiments that were done with replicase preparations to test this hypothesis showed that CP was not required for the synthesis of AMV minus-strand RNA *in vivo* or *in vitro*. This led to the conformational switch model of AMV RNA replication.

An analysis of sequences of AMV RNAs, which direct minus-strand RNA synthesis by the purified viral replicase *in vitro*, showed that the entire 3' terminal homologous sequence of 145 nt is required for minus-strand promoter activity. This promoter consists of the TLS structure formed by the 3'-terminal 112 nt and a hairpin structure, termed hairpin E, between nt 112 and 145 from the 3' end of the RNAs. Hairpin E may be the primary element recognized by the viral replicase, and the TLS could serve to direct the replicase to the very 3' end of the template. If the TLS structure is disrupted by mutations affecting the pseudoknot or if the TLS is completely deleted, hairpin E directs initiation of minus-strand synthesis to a position located 5' from the hairpin. In the absence of the TLS, the mechanism of RNA synthesis directed by hairpin E is very similar to that directed by the sub-genomic promoter hairpin located in minus-strand RNA3, which directs plus-strand RNA4 synthesis. The finding that the sub-genomic promoter hairpin could be replaced by hairpin E without loss of infectivity illustrates the functional equivalence between the two hairpins. Although a knockout mutation of the CP gene does not affect AMV minus-strand RNA synthesis in infected protoplasts or in leaves expressing AMV replicase proteins, it results in a 100-fold drop in the accumulation of viral plus-strand RNAs. The expression of CP in leaves along with the replicase proteins not only enhanced the accumulation of replication-competent RNAs, but also the accumulation of replication-defective viral RNAs. Thus, it is possible that the stimulation of the accumulation of plus-strand RNAs by CP in infected cells reflects a role of CP in protection of the RNAs from degradation.

RNA3 can be replicated *in trans* by P1 and P2 proteins expressed from replication-defective cDNAs RNAs 1 and 2 in tobacco leaves or by P1 and P2 expressed in transgenic P12 tobacco. However, RNAs 1 and 2 are unable to make use of these expressed replicase proteins and are dependent for replication on their encoded proteins *in cis*. This requirement *in cis* explains why RNA3 can replicate in protoplasts of transgenic P12 plants without a requirement for CP, whereas replication of RNA1 or RNA2 in this system requires CP to enable translation of these RNAs. Moreover, replication of RNAs 1 and 2 is strictly coordinated. Mutations in either P1 or P2 ORF that is lethal to the function of the encoded proteins block the replication of both mutant and wild-type RNA1 or 2, but does not affect the replication of RNA3 by the expressed replicase. Apparently, replication of RNA1 controls replication of RNA2 and vice versa.

Virus Encapsidation and Movement

The high-affinity binding sites for CP at the end of RNAs 1 and 2 are dispensable for encapsidation of the RNAs. This was found by the expression of mutant RNAs 1 and 2 without their 3' UTRs along with wild-type RNA3 in leaves expressing replicase proteins. RNAs 1, 2, and 3 were all encapsidated into particles. Possibly, assembly of particles initiates on the identified internal CP binding sites in AMV RNAs.

The RNA3 encoded MP and CP are both required for cell-to-cell movement of AMV in infected plants. The MP is phosphorylated and forms tubular structures on the surface of infected protoplasts, suggesting that virus movement in plants involves transport of virus particles through tubules, which traverse the cell wall through modified plasmodesmata. Such a mechanism has been found for viruses of the families *Bromoviridae*, *Comoviridae*, *Caulimoviridae*, and *Bunyaviridae*. However, tubular structures filled with virus particles have not been observed in AMV infected leaf tissue. Moreover, a CP mutant defective in the formation of virions is able to move cell-to-cell at a reduced level. This suggests, along with information about other members of the *Bromoviridae*, that the transport of AMV moves cell-to-cell as viral ribonucleoprotein complexes that structurally differ from virions.

AMV MP is functional in the cell-to-cell transport of Tobacco mosaic virus, Brome mosaic virus, Prunus necrotic ringspot virus, Cucumber mosaic virus, and Cowpea mosaic virus. Conversely, the MPs of these viruses are competent in systemic transport of AMV as long as the MPs contain the last 44 CP-interacting aa of AMV MP at their C-termini. Analysis of AMV MP and those of other viruses in the family *Bromoviridae* suggests that the C-termini of these MPs enable specificity in virus transport by binding specific virus CPs and that the N-terminal portions of the MPs function in transport.

AMV MP interacts with *Arabidopsis* Patellin 3 (atPATL3) and Patellin 6 (atPATL6), which are implicated in membrane trafficking. The interaction interferes with the plasmodesmatal targeting of the MP and reduces AMV cell-to-cell movement. AMV replicated to higher levels in Patellin knockout mutants of *Arabidopsis* than in normal plants where replication is limited to fewer cells due to inhibition of cell-to-cell movement.

Role of Coat Protein in the AMV Replication Cycle

Natural infections by AMV are initiated by viral particles containing the genomic RNAs 1, 2, and 3, and sub-genomic RNA4. However, inoculation of plants in the laboratory with a mixture of the three genomic RNAs results in barely detectable levels of

AMV, but the infectivity of this mixture is increased 1000-fold by the addition of four to ten molecules of CP per RNA molecule. Alternatively, infectivity can be increased by including RNA4, the messenger for CP. It is assumed that AMV infection starts with the RNAs associated with one or more dimers of the viral CP. These RNA/CP complexes can be generated by partial disassembly of the particles in inoculated cells, by mixing purified viral RNAs and CP *in vitro*, or by translation of RNA4 in the inoculated cells and subsequent binding of *de novo* synthesized CP to the viral RNAs. The requirement of CP for translation of AMV RNAs was explained by the finding that AMV CP mimicks the function of the host cell poly(A) binding protein for efficient translation.

Two alternative models have been proposed for the role of CP in the replication of AMV RNA: a conformational switch model and a 3' organization model. The conformational switch model suggests that AMV RNA 3' ends form two mutually exclusive conformations, one that is extended and binds AMV CP and a second CP-free TLS pseudoknot conformation. This model proposes that CP enhances the translation of RNA 1 and 2 to make the replicase proteins and that the switch from translation to replication requires dissociation of CP from the 3' end of the RNAs to allow the formation of the TLS structure for minus-strand promoter activity. This model is based upon many experiments done *in vivo* and *in vitro* with mutant RNAs or replicase preparations, which found that CP was not needed for minus-strand synthesis. In contrast, the 3' organization model suggests that the CP organizes the 3' termini into compact structures for activation of early RNA replication. This was proposed based on the imperfect fit and uncertain functionality of the reported TLS at the 3' end of AMV RNAs and the crystal structure of the 3' terminal 39 nt of AMV RNA in complex with the RNA binding domain of the CP. This model proposes that a structurally organized RNA end is important for replication for all members of the family *Bromoviridae*. The compact structure is formed at the 3' end of some virus RNAs, such as those of BMV, by a TLS structure, while others, such as the 3' end of AMV and the ilarviruses, require CP binding to fold into the active structure.

Replicase proteins translated from inoculum RNAs 1 and 2 target the viral RNAs to vacuolar membranes where RNA synthesis takes place. The mechanism of the switch from minus-strand to plus-strand RNA synthesis is not yet clear. Although the promoter for plus-strand sub-genomic RNA4 synthesis is structurally similar to hairpin E in the minus-strand promoter, the promoters for plus-strand genomic RNA synthesis have not yet been characterized. The requirement of CP for efficient accumulation of plus-strand RNA in infected cells may reflect a role of CP in protection of the RNAs from degradation, but a role in plus-strand RNA synthesis has not yet been ruled out. There is growing evidence for AMV and other viruses in the family *Bromoviridae* that the many steps in the viral replication cycle are tightly linked.

Virus-Host Relationships

The AMV group is a large conglomerate of strains infecting a large number of susceptible hosts. This accounts for the tremendous range of symptoms displayed by AMV-infected plants. Mutations in the coat protein gene and 5' UTR of RNA3 have been shown to affect symptom formation in tobacco. Cytological modifications in AMV-infected plants occur only in cells of organs showing symptoms. In these cells, fragmentation of the ground cytoplasm and an increased accumulation of membrane-bound vesicles has been observed. Sometimes the lamellar system of chloroplasts is affected and invaginations of the nuclear membrane have been reported. The MP protein localizes to plasmodesmata. It interacts with atPATL3 and atPATL6, which are normally located at the cell periphery, to form complexes that were at the plasmodesmata and also at the cell periphery. Overexpression of atPATL3 and atPATL6 reduces the plasmodesmatal localization of AMV MP thereby reducing the spread of infection. When expressed alone in protoplasts, the P1 protein is found on MVBs, while the P2 protein is throughout the cytosol. When P1 and P2 are expressed together, both are found on MVBs; when both proteins are expressed with a functional AMV RNA, the proteins localize to the vacuolar membrane, the tonoplast, where replication takes place. Following encapsidation, virus particles are found throughout the cytoplasm with a few records of particles in the nucleus. Depending on the strain, the particles form different types of intracellular aggregates.

Recent studies have shown that the CP of AMV is multifunctional and interacts with a number of host proteins. Chloroplast proteins are increasingly found to be associated with virus proteins; *Arabidopsis* PsbP (atPsbP) protein is one example. This nuclear-encoded component of the oxygen-evolving complex of photosystem II was identified in a yeast two-hybrid screen to interact with AMV CP. Newly synthesized atPsbP was sequestered in the cytosol during virus infection, whereas it localizes to the chloroplasts in healthy cells. Overexpression of atPsbP inhibited virus replication suggesting that atPsbP has a role in plant defenses. AMV CP also interacts with the transcription factor, ILR3, in both tobacco and *Arabidopsis*. This interaction takes place in the nucleus where CP-interaction moves ILR3 to the nucleolus in which CP had previously been found. CP has a nucleolar localization signal in its N-terminus and interacts with importin- α to gain access to the nucleus. It is suggested that ILR3-CP interaction leads to a down-regulation of a host factor that is involved in host defense modulation. AMV CP also interacts with atALKBH9B, recently identified as the first demethylase described in plants. Such enzymes have broad regulatory roles in RNA biology and can remove m⁶A in virus RNAs to modulate infectivity of the virus. atALKBH9B also interacts with AMV RNA, whose sequence contains three of the common m⁶A consensus motifs. Down-regulation of atALKBH9B in infected plants increased the abundance of m⁶A in AMV RNA and decreased infection.

Host Range and Economic Significance

AMV occurs worldwide. Strains of this virus have been found in natural infections of about 305 plant species representing 22 families. The experimental and natural host ranges include over 600 species in 70 families. Recently, 68 *Arabidopsis thaliana* ecotypes were analyzed for their susceptibility to AMV infection. In total 39, ecotypes supported both local and systemic infection, 26 ecotypes supported only local infection, and three ecotypes could not be infected.

Fig. 5 Symptoms caused by AMV infection. (A) Interveinal chlorosis on alfalfa plants; (B) Mottle on potato; (C) Vein clearing on Burley tobacco; (D) Mosaic on pepper; (E) Mosaic on soybean; (F) Chlorosis on viburnum; (G) Interveinal chlorosis on white clover; (H) Tip necrosis on lentil. From: (A) South Dakota State University, extension.sdstate.edu; (B) Howard F. Schwartz, Colorado State University, Bugwood.org; (C) Kenneth Seebold, University of Kentucky, burleytobaccoextension.ca.uky.edu; (D) Whitney Cranshaw, Colorado State University, Bugwood.org; (E) Craig Grau, University of Wisconsin, cropprotectionnetwork.org; (F) Tom Creswell, Purdue University; (G) Barenbrug agriseeds, agriseeds.co.nz; (H) agriculture.vic.gov.au.

AMV causes significant losses in forage crops, can reduced winter survival, and increase the susceptibility to other pathogens. AMV is an economically important pathogen in temperate pulses (chickpeas, faba beans, field peas, and lentils), pasture legumes (alfalfa, and clovers), and may infect pepper, tobacco, tomato, soybean, potato, celery, weeds, and ornamental plants. In alfalfa, losses have been reported up to 30% and seed production up to 69%. In soybean, AMV infection along with soybean mosaic virus causes disease synergism with the development of severe symptoms. Such co-infection is of concern in areas where the soybean

aphid is present. Time of infection is important in yield loss caused by AMV. For example, late infection of faba bean can cause up to 45% of seed loss.

Symptoms caused by AMV vary depending upon the virus strain and host, but include: yellow mosaic and mottle, necrosis, stunting, leaf distortion, leaf rolling, vein-clearing, chlorotic spots, line patterns, and ringspots. The environment plays a role in symptom production. Infected field plants are more symptomatic in cool spring and autumn weather and may be symptomless in warm/hot summers. [Fig. 5](#) shows the symptoms for a variety of infected plants.

Transmission

AMV is easily mechanically transmissible. However, field spread occurs predominantly by aphid transmission. At least 15 aphid species are known to transmit the virus in a stylet-borne or non-persistent manner. Acquisition of the virus occurs within 10–30 s of feeding and is followed by immediate transmission without a latent period. The ability of the aphid to continue to transmit is lost within 1 h. The variability of individual aphid species in their capacity to transmit different AMV strains suggests a specific virus–vector relationship which is probably governed by the structural properties of the CP. Seed transmission of AMV has been reported for alfalfa and other plant species with rates of transmission varying from 0.1% to 50%. Transmission of the virus between plants by parasitic dodder has been observed with five *Cuscuta* species.

Epidemiology and Control

Genes conferring resistance to AMV have been reported in alfalfa (*amv-1* gene), soybean (*rav1* gene), and tomato (*am* gene). These, however, have not been deployed in commercial crops. Control of AMV in alfalfa is primarily achieved by using virus-free seed and avoiding reservoir hosts of the virus. Because AMV infection occurs naturally in many different plant species, control is difficult.

Transgenic tobacco, alfalfa, and white clover plants expressing the CP gene of AMV were found to be highly resistant to the virus when mechanically inoculated. The resistance was clearly protein-mediated because plants with the highest levels of CP accumulation were the most resistant. A mutation in the transgene that affected the N-terminal sequence of the encoded CP destroyed resistance to the wild-type virus but the mutant transgene conferred resistance to virus expressing the mutant CP. As yet, transgenic resistance to AMV has not been commercialized.

AMV is primarily spread by aphids. The incidence of AMV in alfalfa pastures can be as high as 50%–98%. Susceptible crops growing outdoors or in greenhouses close to alfalfa fields are at risk of infection. Because of AMV's wide host range, many weed species and ornamental plants are infected, which provides reservoirs for the aphids to acquire the virus. AMV is also seed-borne. It has been spread throughout the world by importation of infected alfalfa seed lots. AMV is also mechanically transmitted. It can be transmitted to healthy plants by handling infected plants or seedlings.

Control of AMV in alfalfa is primarily achieved by using virus-free seed and transplants, managing weeds, and avoiding reservoir hosts of the virus. Insecticides are largely ineffective in field management of AMV because aphids do not have to colonize a plant to acquire or transmit the virus; test feedings are sufficient. However, control of aphids early in the season may avoid buildup of populations. Various cultivars of crop plants may vary in susceptibility; however, there are no AMV-resistant commercial varieties.

Glossary

3'-co-terminal sub-genomic RNA Virus-specific RNA corresponding to the 3'-terminal portion of virus RNA genome.
Cap m⁷GTP moiety at the 5' end of the genomic virus RNA.
Cell-to-cell movement Substance movement between adjacent cells.
Coat protein Virion protein directly covering the virus genomic nucleic acid in the particle.
Endoplasmic reticulum Cell network of endomembrane tubules.

Long-distance movement Substance virus movement through the plant phloem system.
Movement protein Virus protein responsible for cell-to-cell movement.
Open reading frame Sequence of codons (usually not less than 15–20 codons) containing no termination triplets.
Triple gene block The module of three overlapping genes involved into cell-to-cell and long distance movement of the virus.

Introduction

The family *Alphaflexiviridae* (order *Tymovirales*) contains seven genera (*Allexivirus*, *Botrexvirus*, *Lolavirus*, *Mandarivirus*, *Platypuvirus*, *Potexvirus*, and *Sclerodarnavirus*) and five species unassigned to a genus (Tables 1 and 2). These viruses have flexuous filamentous particles (Fig. 1) and infect higher plants or fungi. The 5'-capped and 3'- polyadenylated monopartite positive-stranded RNA genomes of the *Alphaflexiviridae* members are 5.9–9.0 kb in length. The 5'-terminal open reading frame (ORF) encodes the replicase with conserved methyltransferase (MTR), helicase (HEL), and RNA-dependent RNA polymerase (POL) domains, a configuration typical of the alphavirus-like superfamily of plant and animal viruses (Fig. 2). Most plant-infecting alphaflexivirus genomes encompass the module of three overlapping ORFs (Triple Gene Block, TGB) that are necessary for the cell-to-cell movement. Coat protein (CP) is encoded by the gene located at or close to the 3'-end of the genome (Fig. 2). Alphaflexiviruses produce 3'-coterminal sub-genomic RNAs that allow expression of the CP and other accessory proteins. Some alphaflexiviruses amplify to high yields in host plants, and are transmitted mechanically, whereas others have mites and insect vectors. Plant-infecting family members have been found in a wide range of mono- and dicotyledonous plants species, and the majority of them have only mild effects on their host.

Taxonomy, Phylogeny of Family Members, and Evolution

The genera of *Alphaflexiviridae* show close similarity of the encoded proteins (mostly the replicases) and share common features of the virion structure and genome organization. These properties are shown in Fig. 2 and Table 1. The affiliation with *Alphaflexiviridae* is based on the replicase amino acid sequence, and viruses from different genera usually have less than about 45% nt identity in the respective replicase genes.

Table 1 Some properties of the viruses in the genera of the family Alphaflexiviridae

Genus	Host	Virion length	Number of ORFs	Replicase size (kDa)	Coat protein size (kDa)
<i>Allexivirus</i>	Higher plants	800 nm	6	170–195	25–29
<i>Botrexvirus</i>	Fungi	720 nm	5	160	43
<i>Lolavirus</i>	Higher plants	640 nm	6	196	32
<i>Mandarivirus</i>	Higher plants	650 nm	6	187	34
<i>Platipuvirus</i>	Higher plants	800 nm	7	157	22
<i>Potexvirus</i>	Higher plants	470–580 nm	5	150–195	18–27
<i>Sclerodarnavirus</i>	Fungi	No virions	1	193	No CP

Among the plant-infecting Alphaflexiviridae five genera are currently recognized (*Potexvirus*, *Allexivirus*, *Lolavirus*, *Mandarivirus*, and *Platipuvirus*; Table 2). The most populated genus *Potexvirus* includes 38 members (Table 2). The next most populated genus *Allexivirus* contains 12 approved members. The genus *Lolavirus* contains two members, whereas each of the genera *Mandarivirus* and *Platipuvirus* includes only a single species. Two remaining fungus-infecting genera also include a single species (Table 2).

The single member of the genus *Botrexvirus* (*Botrytis virus X*) infects a filamentous fungus. The BVX genome lacks the movement protein genes, but encodes the CP and several unique proteins of unknown function. Another fungus-infecting genus *Sclerodarnavirus* is also represented by a single species whose genome contains only the replicase ORF (Fig. 2 and Table 2).

Phylogenetic trees based on the nucleotide and protein sequences depended on the genome region used for analysis. In a phylogenetic analysis of the whole replication protein, *Botrexvirus* and *Allexivirus* genera fall on a well-supported separated branch (Fig. 3). *Potexvirus*, *Mandarivirus* and *Lolavirus* genera form another branch in replicase phylogenetic tree, whereas *Platipuvirus* (DOSV) forms the most basal branch in this dendrogram (Fig. 3). If the genome nucleotide sequence is considered, the genomic RNAs of Alphaflexiviridae are most closely related to those of the other families in the order Tymovirales, namely Betaflexiviridae, Gammaflexiviridae and Tymoviridae. Strikingly, in this genome-based tree two genera of betaflexiviruses, namely *Vitivirus* and *Tepovirus*, show common root with the Alphaflexiviridae branch but not with the other members of Betaflexiviridae (Fig. 4). This is in line with replicase protein tree where *Vitivirus* and *Tepovirus* proteins form clear distinct branch separated from the rest of betaflexiviruses (Fig. 3).

The TGB proteins are related to the equivalent proteins encoded by some members of the family Betaflexiviridae and, more distantly, to those of the rod-shaped viruses in the family Virgaviridae (genera *Hordeivirus*, *Pecluvirus*, and *Pomovirus*).

Virion Structure

Typical alphaflexiviruses have flexuous filamentous particles (12–13 nm in diameter and up to 800 nm in length) with helical symmetry (pitch of ca. 3.4 nm) (Fig. 1). No lipids have been reported in the virions of alphaflexiviruses. Usually no carbohydrates are associated with the virions. The potexvirus and lolavirus CPs are reportedly glycosylated. The viral capsid of most members of the family (except lolaviruses) is composed of identical CP subunits ranging in size from 18 to 43 kDa. In allexiviruses, the 42 kDa protein (encoded in the third ORF from the 3' end; Fig. 2) is a minor virion component non-uniformly distributed along the particle. The particles of lolaviruses are composed of equimolar amounts the larger and smaller versions of the CP (32 kDa and

Fig. 2 Schematic representation of the genome structure of the *Alphaflexiviridae* (*Potexvirus*, Potato virus X; *Alexivirus*, Shallot virus X; *Mandarivirus*, Citrus yellow vein clearing virus; *Botrexvirus*, Botrytis virus X; *Sclerodarnavirus*, *Sclerotinia sclerotiorum* debilitation-associated virus; *Lolavirus*, Lolium latent virus; *Platipuvirus*, Donkey orchid symptomless virus). Arrowheads denote the 3'-termini of genomic RNAs; broken arrows – the start and direction of the potexvirus sub-genomic RNAs. Open reading frames (ORFs) are shown by boxes. MTR, HEL, and POL stand for the conserved methyl-transferase, NTPase/helicase, and RNA polymerase domains, respectively. TGB (triple gene block), CP (coat protein gene), and the genes for RNA-binding proteins are shown as boxes with different fills.

28 kDa, respectively). The 28 kDa CP seemingly originates from internal translation initiation of the coat protein gene. It should be noted that the sclerodarnavirus exists only as a capsid-less single-stranded and double-stranded RNA, making an intriguing parallel with capsid-less RNA agents associated with chestnut blight hypovirulence (family *Hypoviridae*) that code for the replicase orthologs of plant picorna-like viruses of the family *Potyviridae* (Fig. 2).

Genome Organization

Genomic RNAs of plant alphaflexiviruses typically have five or six ORFs. The 5' terminal ORF1 encodes the viral replicase (Fig. 2). The 3' proximal ORFs encode the movement proteins (TGB proteins), the CP, and an accessory zinc-binding and RNA-binding protein (Fig. 2). The last protein is encoded only in genera *Alexivirus* and *Mandarivirus*. ORF2 to ORF5 are expressed via the 3' co-terminal sgRNAs (Fig. 2).

^apartial sequence.

Fig. 3 Maximum-likelihood tree derived from the complete amino acid sequences of the replicases of representative members of the families *Betaflexiviridae* and *Alphaflexiviridae*. Names of viruses and GenBank accession numbers are shown in the tree. Bootstrap analysis was done using 1000 replicates in MEGA7. The newly identified virus in this study is indicated by a red star. The scale bar represents the genetic distance. Accession number for Loquat virus A genome is MK936045. After Liu, Q., Yang, L., Xuan, Z., *et al.*, 2020. Complete nucleotide sequence of Loquat virus A, a member of the family *Betaflexiviridae* with a novel genome organization. *Archives of Virology* 165, 223–226.

Notable specific feature of *Allexivirus* members is the absence of TGB3 gene and the presence, in place of TGB3, of the gene for a large protein of unknown function (Fig. 2). Even more distinctive features in genome structure have been found in an unusual *Platipuvirus*, Donkey orchid symptomless virus (DOSV) (Fig. 2). The ORF1 that overlaps the replicase gene has marginal similarity with MPs of plant tymoviruses (family *Tymoviridae*). The replicase gene (ORF2) shares domain organization of the encoded protein with other members of the family *Alphaflexiviridae*. A 44 kDa protein encoded by ORF3 shows low level of identity with myosin. The putative 25 kDa movement protein (MP) (ORF7) shares low level of identity with the 3A-like MPs of some members of the family *Tombusviridae* (*Dianthovirus*).

Fig. 4 Molecular Phylogenetic analysis of full-genome tymoviral reference sequences by Maximum Likelihood method based on the General Time Reversible model with a discrete Gamma distribution. The scale bar represents the genetic distance. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. After Çağlayan, K., Roumi, V., Gaze, L.M., *et al.*, 2019. Identification and characterization of a novel Robigovirus species from sweet cherry in Turkey. Pathogens 8, 57.

In genus *Potexvirus*, three 3' co-terminal sgRNAs are produced in infected plant cells (Fig. 2). The 2.1 kb species serves as mRNA for the TGB1 protein, whereas the 1.2-rb sgRNA directs expression of the TGB2 and TGB3 via leaky scanning. The 1.0-kb sgRNA encodes the coat protein. The genome organization of the TGB-containing alphaflexiviruses is quite similar to the TGB-containing betaflexiviruses belonging to the subfamily *Quinvirinae* (genera *Carlavirus*, *Robigovirus* and *Foveavirus*). Fungal alphaflexiviruses (genera *Botrexvirus* and *Sclerodarnavirus*) are drastically different with respect to their genome architecture. The capsid-less sclerodarnavirus encodes the replicase gene only, whereas *Botrytis virus X* contains six genes encoding replicase, CP and four proteins with unknown function (Fig. 2).

Properties and Functions of Gene Products

The ORF1 product contains the invariant array of protein domains involved in RNA capping (MTR), duplex unwinding (HEL), and RNA synthesis (POL) (Fig. 2). The POL domain of potexviruses is vital for the functioning of the viral replication complex. It contains the typical signature of plus-RNA viral RdRp – tripeptide GDD. Mutational analysis of potexvirus genomes unambiguously showed that during the catalysis of polymerization reaction this motif has the essential role. The POL domain of potexviruses also recognizes the cis-signals in the 3'-terminal region of both the positive and negative strands of RNA genome (see also below). These specific protein–RNA interactions allow correct initiation of the replication.

The replicative HEL domain of potexviruses locates in the middle of replicase protein and belongs to SFI helicase family. The purified HEL is able to unwind dsRNAs and to remove the γ -phosphate from nucleoside triphosphates. Both of these activities depend on Mg^{2+} or Mn^{2+} cations. Mutations of the SFI conserved motifs I, II, III, or VI resulted in inhibition of these activities. The RNA binding activity of HEL is cooperative and is based on conserved motifs I and II as well as on poorly conserved aa sequences.

The N-terminal viral replicase MTR domain was proposed to have an AdoMet-dependent guanylyl-transferase activity which transfers the methyl group of AdoMet to GTP, leading to m^7 GTP formation. The m^7 GMP moiety of m^7 GTP is then transferred to the 5' end of the genomic RNA via the covalent [m^7 GMP-enzyme] intermediate. Analogous cap formation mechanisms have been found also in other members of the alphavirus-like superfamily of positive strand RNA viruses. Importantly, the first two domains

of potexvirus replicase (MTR and HEL) work in a concert to form the 5' cap-structure on the nascent viral genomic and sub-genomic RNAs.

The potexvirus TGB1 product also contains an NTPase-helicase domain of SF1 with seven conserved motifs (I, Ia, II, III, IV, V, and VI). Motif I ("Walker A") includes typical GKS/T tripeptide, and motif II ("Walker B") is involved in binding of ATP and Mg^{2+} . The TGB1 protein is necessary for the cell-to-cell movement and also functions as a suppressor of RNA silencing. It seems that these activities of the TGB1 are uncoupled. In recent years it was documented that potexvirus TGB1 also participates in formation of virus replication factories in infected cells. Thus, the PVX TGB1 is involved in reorganizing actin cytoskeleton and endoplasmic reticulum (ER) into the membrane-bound virus replication complexes (VRC). Moreover, TGB1 participates in positioning the VRC close to plasmodesmata thus helping to establish connection between replication and movement.

The TGB2 and TGB3 proteins, containing blocks of hydrophobic residues, are associated with membranes derived from the ER. Potexvirus TGB2 protein has two predicted transmembrane domains that interact with ER membranes. It seems that TGB2 protein integrates into the ER membranes in a U-like structure, with the central part positioned in the ER lumen and the N- and C-termini located on the cytoplasmic side of the ER. Mutation analysis revealed that two conserved cysteine residues in the C-terminal region of potexvirus TGB2 protein are important for the cell-to-cell movement. Recently, it was found that PVX TGB2 may function as the molecular bridge allowing interaction between the VRC and TGB1, TGB3, and coat protein, thereby enhancing the efficiency of the virus spread in infected plant tissue.

Potexvirus TGB3 protein also has a conserved C(x₅)G(x₆₋₉)C sequence positioned at the C-terminus of a predicted transmembrane domain. This C-terminal sequence is exposed to the cytoplasmic side of the ER and contains a sorting signal that is necessary for TGB3 oligomerization and for the targeting of cortical ER.

Replication and Propagation

Cis-acting replication signals have been mostly studied using PVX and Bamboo mosaic virus (BaMV) as models. Replication of potexviruses is governed by the cis-signals at the 5' - and the 3' end of the genome (each representing a complex tertiary RNA structure). The synthesis of the negative strand and of the positive-strand genomic and sub-genomic RNAs requires long-distance interactions between the conserved sequences at the 3' ends of the positive and negative RNA strands, and the internal complementary octanucleotides. The consequence of the replication/transcription events is as follows: (1) using genomic RNA as template, the replicase recognizes the 3'-cis-signal base-paired with an internal octanucleotide and synthesizes the antigenomic (negative) RNA strand; (2) in the negative strand, the replicase interacts with the 3'-cis-signal base-paired with an internal octanucleotide and produces the progeny genomic RNA strands; (3) in the negative strand, contacts of the 3'-cis-signal with complementary octanucleotides localized, in 3' to 5' direction, prior to the genes for TGBp1, TGBp2, and CP, force the replicase to initiate internally and produce the respective sgRNAs.

Transmission, Host Range

Most members of the family infecting higher plants are transmitted by mechanical contacts, seeds, or grafting. Citrus yellow vein clearing mandarin virus (CYVCV) is spread from infected to healthy citrus trees by the whitefly *Dialeurodes citri* (Ashmead). Alexiviruses are transmitted by eriophyid mites. PVX causes mild mosaic or a symptomless infection in solanaceous hosts, depending on the virus strain. In *Gomphrena globosa* L., a diagnostic host, the virus induces formation of ring necrotic lesions. Another potexvirus, PepMV causes tomato fruit discoloration (marbling, blotchy ripening and flaming), leaf distortion, chlorosis, yellow spots, interveinal leaf yellowing (Fig. 5) and, occasionally, leaf and stem necrosis. In addition, CYVCV infection in lemon and sour orange is characterized by strong yellow vein clearing, leaf distortion, ringspot lesions, and veinal necrosis. The natural host range of the family members vary from narrow (lollaviruses, mandarinviruses, and the viruses infecting fungal hosts) to moderate (potexviruses).

Epidemiology and Control

The genus *Potexvirus* includes species that are responsible for serious crop damage (PVX, BaMV, Pepino mosaic virus, and Citrus yellow vein clearing virus), whereas the economical impact of other family members is limited or not important. Phytosanitary control measures are used to diminish the virus spread in vegetatively propagated crops. Application of cross-protection with mild viral strains, which proved effective against damaging crop pathogens like PepMV, has been proposed. Transgenic plants of tobacco, tomato, and orchid, resistant to some potexviruses have been produced; they may have a potential for virus control.

Virus-Host Relationships

Alphaflexiviridae members are replicated in the cytoplasm of infected host cells. Infection is accompanied by formation of ER-derived vesicles that serve as replication sites (virus fabrics). Other cytopathic effects are the fibrous, beaded, banded, or irregular aggregates in the cytoplasm and, occasionally, in the nucleus.

Fig. 5 Interveinal leaf yellowing symptoms after inoculation of RNA transcripts of PepMV infectious clone P-5-IYflc (variety Moneymaker). After Hasiów-Jaroszewska, B., Paeleman, A., Ortega-Parra, N., *et al.*, 2013. Ratio of mutated versus wild-type coat protein sequences in Pepino mosaic virus determines the nature and severity of yellowing symptoms on tomato plants, *Molecular Plant Pathology* 14, 923–933.

On the molecular level, virus-host interactions involve contacts of the replicase and the movement proteins of the plant-infecting alphaflexiviruses with a variety of host factors that are required for efficient infection. After entering the host cell, the virus RNA genome is used as template for translation and replication. Several host factors involved in the movement of the potexvirus were identified. First, potexvirus TGB3 exhibits the affinity to highly curved subdomains of cortical ER, targets membrane bodies at the cell periphery and directs the TGB2 protein to these structures. Second, a serine/threonine kinase-like protein from *N. benthamiana* (NbSTKL) was demonstrated to be upregulated in BaMV infection and to be critical for the cell-to-cell movement. It is suggested that NbSTKL modifies a specific protein factor that regulates plasmodesmata (PD) gating for virus trafficking. In addition, another kinase, casein kinase 2 α (CK2 α), which interacts with BaMV CP in PD, can be involved in releasing viral RNA from the movement RNP after the passage of the latter through PD. Third, RabGTPase-activating protein (GAP or NbRabGAP1), is involved in the intercellular and systemic movement of the BaMV potexvirus. Rabs, a family of small GTPases, is involved in all aspects of intracellular vesicle budding, targeting, docking, and fusion. It was shown that NbRabGAP1 activates one of the RabGTPases to support the activity of the TGB proteins in transferring the viral movement complex through plasmodesmata. Involvement of NbRabGAP1 in the BaMV movement suggests that this movement is associated with the vesicle turnover pathway.

Recently, several potential host factors affecting BaMV replication have also been identified. Among them, cytoplasmic 5' $\rightarrow$ 3' exoribonuclease NbXRN4 promotes potexvirus replication, most probably, by removing uncapped genomic and subgenomic RNAs that are produced during replication/transcription as aberrant transcripts. At the replication stage, the 3' untranslated region (UTR) of the potexvirus genomic RNA plays an important role in capturing several host factors assisting the RNA synthesis. Glutathione transferase U4 (NbGSTU4), chloroplastic PGK (chlPGK), and heat shock protein 90 (Hsp90), were found to interact with the 3' UTR of BaMV. The protein chlPGK interacts with 3' UTR and seems to be vital for transmitting viral RNA and the replicase, to chloroplasts. The advantage of BaMV RNA targeting to the chloroplast can be explained by isolation of the VRC from the host protection systems, i.e., RNA silencing. The large viral RNA-protein complex including viral RNA, replicase, and possible host factors enters into chloroplasts, assisted by the Hsp90 acting as chaperone in protein complex folding and protein translocation across membranes. NbGSTU4, a protein involved in antioxidant protection, also stimulates BaMV replication. As soon as BaMV RNA and VRC components enter chloroplasts, they face the danger of high levels of reactive oxygen stress (ROS), since the chloroplast is one of the main producers of ROS. Movement of NbGSTU4 into chloroplasts along with BaMV RNA and the bound glutathione may play a role in eliminating the effects of ROS. Importantly, NbGSTU4 can interact with 3' UTR at physiological glutathione concentrations. Additionally, the S-adenosyl methionine synthetase and the respiratory explosion oxidase homolog were found to stimulate the BaMV replication.

ER and myosins are employed in movement of potexviruses. Although the ER membrane allows the transport of membrane-associated molecules by diffusing within the lipid layer, the mobility of the ER membrane as well as the ER-directed transport of macromolecules is controlled by the ER-associated actin-myosin system. In accordance with this, the directed targeting of TGB proteins to PD and, consequently, the spread of infection also depends on actin and myosin activity.

Antiviral plant protection is also controlled by complex interactions of host and viral factors. For example, antiviral reactions may be associated with nonsense-mediated degradation pathways of mRNA decay (NMD), which is a conservative mRNA quality control mechanism and selectively eliminates aberrant transcripts containing unusually long non-coding 3' terminal sections. By recognizing such viral RNAs and directing them to degradation, NMD neutralizes viral infection and functions as a viral restriction mechanism. A genetic screen in *A. thaliana* found that inactivating mutations in the UPF1 gene, which is a key NMD factor, increase the susceptibility of plants to PVX infection.

Alphaflexiviruses produce dsRNA as an intermediate in replication, making them targets for RNA silencing mechanism initiated by Dicer-like ribonucleases (DCL). After formation, siRNAs bind to AGOs, which are part of RISCs, to form a molecular platform for RNA silencing mechanism. To counteract RNA silencing, alphaflexiviruses express RNA silencing suppressors (VSRs) that inhibit various steps of RNA silencing. Thus, the potexvirus TGBp1 and mandarivirus CP act as VSRs. The TGBp1 of several potexviruses has been shown to have VSR activity inducing destabilization of AGO proteins. On the other hand, the PLAMV TGB1 protein inhibits secondary siRNA production by targeting the RDR6 pathway and additionally affects the AGO4 transfer from nucleus to cytoplasm.

As alternative to RNA-targeted protective mechanisms, plants have developed a variety of resistance (R) proteins that can detect pathogen-associated molecular patterns (PAMPs) and induce protective reactions. Such detected effectors are called avirulence proteins (Avr). Most R-gene products have leucine-rich repeat domains (LRR) associated with the assumed nucleotide-binding site domain (NBS). Recent studies have identified molecular factors that affect the accumulation of NB-LRR and, consequently, the expression of resistance. Among them, the “susceptibility factor essential for potexvirus accumulation” (EXA1) protein containing the glycine-tyrosine-phenylalanine (GYF) domain was identified as a negative regulator of NB-LRR protein accumulation and, as a result, involved in plant immunity. It is interesting that mutations affecting GYF domain protein EXA1 are also involved in resistance to potexviruses. Plantago asiatica mosaic virus (PLAMV), Alternanthera mosaic virus (AltMV), and PVX show significantly suppressed ability to establish infection in the absence of EXA1. Some plants contain a single *EXA1* gene in their genomes. However, other plants, particularly *N. benthamiana*, soybean, and banana, encode multiple genes. It was found that EXA1 proteins are important factors for successful potexvirus infection in a variety of plant species.

Translation elongation factor eEF1a has been shown to regulate the RNA replication of potexviruses. As the eEF1a binding site in the 3′ UTR of BaMV genome overlaps with the RdRp recognition site, eEF1a can play a role in template switch that blocks viral replication during translation. NADP⁺-dependent isocitrate dehydrogenase, MAP kinase, phosphatase-like protein, and proliferating cell nuclear antigen (PCNA) also appear to suppress potexvirus replication.

Recently, it was shown that phosphorylation of REMORIN protein changes its membrane dynamics. PVX TGBp1 is able to activate protein kinase(s), which in turn phosphorylate REMORIN1.3. Since phosphorylated REMORIN is associated with PD closure by induction of callose deposition, this protein causes the reduction of PD permeability and thereby restriction of viral cell-to-cell movement.

Diagnosis

Diagnosis of viruses belonging to *Alphaflexiviridae* mostly relies on serological tests (enzyme-linked immunosorbent assay) and reverse transcriptase PCR methods, including the modifications of the latter like triplex PCR and droplet digital PCR.

Satellite RNAs Associated With Infections of *Alphaflexiviridae*

The only satellite RNAs (satRNAs) so far known to accompany the infections of *Alphaflexiviridae* are those associated with BaMV potexvirus. The satRNAs are variable in sequence, but have the 5′- and 3′ terminal hairpins resembling the cis-signals at the helper BaMV RNA termini. The vital functions provided by the helper BaMV to satRNAs are replication, encapsidation, and cell-to-cell movement. Co-replication of satRNAs has pronounced negative effect on the helper virus propagation. One of the BaMV satRNAs encodes a 20 kDa nonstructural protein which preferentially binds to the satRNA and promotes its long-distance transport in BaMV-infected *N. benthamiana*. The use of transgenic plants expressing satRNAs to control BaMV infection has been considered.

Nomenclature

CR-M Common region major
CR-SL Common region stem-loop
mRep Master replication-associated protein
ORF Open reading frame

PTGS Post-transcriptional gene silencing
Rep Replication initiator protein
ssDNA single-stranded deoxyribonucleic acid
TGS Transcriptional gene silencing

Glossary

Post-transcriptional gene silencing An epigenetic process for regulation of gene expression that results in the mRNA of a particular gene being destroyed. Post-transcriptional gene silencing is believed to protect the organism's genome from, among other things, transposons and viruses.

Rolling-circle replication A mechanism of DNA replication that synthesizes multiple copies of circular molecules of DNA. Rolling circle replication is initiated by an initiator protein that nicks one strand of a double-stranded, circular DNA molecule. The initiator protein remains bound to the 5' phosphate end of the nicked strand and the free 3' hydroxyl end is released to serve as a primer

for DNA synthesis using the unnicked strand as a template; replication proceeds around the circular DNA molecule, displacing the nicked strand as single-stranded DNA.

Satellite like molecule A self replicating molecule which depends on helper virus for movement, encapsidation and transmission.

Transcriptional gene silencing An epigenetic process for regulation of gene expression that results from DNA methylation and histone modifications. Transcriptional gene silencing is believed to protect the organism's genome from, among other things, transposons and integrated viruses.

Introduction

Viruses of the family *Nanoviridae*, some begomoviruses (genus *Begomovirus*, family *Geminiviridae*) and, in one case reported so far, a mastrevirus (genus *Mastrevirus*, family *Geminiviridae*) may be associated with additional circular ssDNA components that are known as alphasatellites. Recently coconut foliar decay, a severe disease of coconut palms in Vanuatu, has been shown to be associated with a multipartite ssDNA virus that is distinct from nanoviruses and geminiviruses and to be associated with multiple (possible) alphasatellites. The association with alphasatellites may thus extend to three families of plant-infecting ssDNA viruses.

Nanoviruses (family *Nanoviridae*) are multipartite ssDNA viruses that infect plants and are transmitted by aphids. The genomes of nanoviruses are composed of 6–8 circular components, each ~1100 nt in size, separately encapsidated in isometric particles. The component known as DNA-R encodes the master replication-associated protein (mRep) that is responsible for *trans*-replication of all *bona fide* virus components. mRep recognises the origin of replication (*ori*) which sits in the common region stem-loop (CR-SL), conserved between all *bona fide* virus components, and initiates rolling circle replication by nicking within the nonanucleotide sequence TAGTATTAC that forms part of the loop of a predicted stem-loop structure. The *bona fide* nanovirus components also contain a second conserved sequence known as the common region major (CR-M).

Geminiviruses (family *Geminiviridae*) are plant-infecting viruses with geminate (twinned quasi-icosahedral) particles that are transmitted by insect vectors. Begomoviruses (genus *Begomovirus*) have either monopartite or bipartite genomes and are transmitted by the whitefly *Bemisia tabaci* whereas mastreviruses (genus *Mastrevirus*) have monopartite genomes and are transmitted by specific leafhoppers.

The first alphasatellite was identified in association with the nanovirus *Subterranean clover stunt virus* in 1995. Sequencing of the genomic components of the virus highlighted the presence of more than one component encoding a replication-associated protein, a feature that was shown for all subsequently characterized nanoviruses. Realisation that the additional Rep-encoding components are satellites came with the demonstration that only the mRep has the capacity to direct replication of the other genome components using infectious clones. The first geminivirus-associated alphasatellite was identified in 1999 in cotton affected by Cotton leaf curl disease (CLCuD). *Cotton leaf curl Multan alphasatellite* was identified fortuitously, by shotgun-cloning, in the search for additional components responsible for the symptoms of CLCuD in cotton. The symptoms were subsequently shown to be encoded by a component we now know as a betasatellite (family *Tolycusatellitidae*; genus *Betasatellite*).

Fig. 1 Comparison of the structures nanovirus- and geminivirus-associated alphasatellites in comparison to the DNA-R genomic components of nanoviruses. The diagram shows the position of the replication-associated protein (Rep), the TATA box of the presumed Rep promoter, an adenine rich sequence (A-rich) in geminivirus-associated alphasatellites, as well as the common region major (CR-M) and common region stem-loop (CR-SL) of nanovirus DNA-R components that is conserved between all *bona fide* nanovirus genome components. All components have a predicted stem-loop structure (at position zero) with, in most cases, the nona-nucleotide sequence TAGTATTAC forming part of the loop. This likely forms the origin of virion-strand DNA replication that is nicked by Rep to initiate rolling-circle replication. Note that the DNA-R components of some nanoviruses contain an additional open reading frame (ORF) known as ORF 1.

Classification

The additional circular ssDNA components associated with nanoviruses and geminiviruses are classified in the recently established family *Alphasatellitidae*. The family encompasses two subfamilies, *Nanoalphasatellitinae* and *Geminialphasatellitinae*, to accommodate the nanovirus and geminivirus alphasatellites, respectively. At present the subfamily *Nanoalphasatellitinae* encompasses seven genera and 19 species, whereas the subfamily *Geminialphasatellitinae* encompasses 4 genera with 43 assigned species. Additionally a divergent possible alphasatellite, associated with coconut foliar decay disease, has been assigned to a species but not a subfamily. Within this classification structure alphasatellites are assigned based on sequence and phylogenetic relatedness.

Structure of Alphasatellites

In common with the DNA-R component of nanoviruses, the alphasatellites encode a Rep protein and have a predicted stem-loop structure with, in most cases, the nona-nucleotide sequence TAGTATTAC forming part of the loop (Fig. 1). Alphasatellites associated with nanoviruses have a size typical of nanovirus components (~1100 nt), but lack the conserved CR-SL and CR-M of their helper viruses and consequently are unable to *trans*-replicate the *bona fide* genome components of their helper viruses.

Typically the geminivirus-associated alphasatellites comprise ~1400 nt, being significantly larger than nanovirus components and nanovirus-associated alphasatellites. The size difference is due to the presence in geminivirus-associated alphasatellites of a sequence rich in adenine and a larger Rep-encoding gene (Fig. 1). The size difference is likely necessary for the movement and/or encapsidation of geminivirus alphasatellites by their helper viruses. Geminiviruses have a stringent size surveillance mechanism that operates during virus movement within the plant as well as size constraints for encapsidation. Being approximately half the geminivirus genome length (~1400 nt), geminalphasatellites may possibly be encapsidated in isometric (half geminate) virions. (Fig. 2).

Likely Origins of Alphasatellites

Based on sequence relatedness it is likely that nanoalphasatellites evolved from the DNA-R components of nanoviruses that were captured by a second nanovirus during a co-infection. A similar “capture following co-infection” mechanism may have resulted in the geminalphasatellites, although the progenitor DNA-R then needed to adapt, by size increase, for efficient maintenance by a geminiviruses. Consistent with this hypothesis it is interesting to note that, having been uncoupled from the mechanism which controls the relative titers of *bona fide* nanovirus components, alphasatellites of both nanoviruses and geminiviruses in many cases vastly exceed the titers of their helper virus component(s) in plants.

It is interesting to note that vast majority of geminivirus-associated alphasatellites from the Old World have been identified in association with monopartite begomoviruses infections that also include a betasatellite (family *Tolecasatellitidae*). In the New World, where only very few monopartite begomoviruses and no betasatellites have been identified, alphasatellites have only so far been reported to occur in association with bipartite begomoviruses. In contrast, nanoviruses have only been identified in the Old World, which may suggest that the association of alphasatellites with geminiviruses evolved in the Old World, although when this occurred is unclear.

Fig. 2 (A) Maximum likelihood phylogenetic tree of representative geminivirus-associated alphasatellite sequences from each species. (B) Maximum likelihood phylogenetic trees of the nanovirus-associated alphasatellite sequences. Trees are inferred using IQ-TREE with TIM2 + F + I + G4 chosen as the best fit model. Branches with less than 60% bootstrap support have been collapsed. The Maximum likelihood phylogenetic tree on the left is a guide for genera demarcation with the cyan line showing the rough 67% genus demarcation threshold. Both trees reproduced from Briddon, R.W., Martin, D.P., Roumagnac, P., *et al.*, 2018. Alphasatellitidae: a new family with two subfamilies for the classification of geminivirus- and nanovirus-associated alphasatellites. Archives of Virology 163, 2587–2600. doi:10.1007/s00705-018-3854-2.

Life Cycle/Epidemiology

Alphasatellites replicate autonomously of their helper viruses in the nuclei of permissive host cells by rolling circle replication. For all other functions alphasatellites depend upon factors provided by their helper viruses including movement within/between cells, and encapsidation for transmission between plants. However, there appears to be little, if any, specificity for helper virus of a particular alphasatellite. For example, the geminalalphasatellite *Ageratum yellow vein Singapore alphasatellite* (AYVSGA; genus *Ageyesisatellite*), which was identified in association with the OW monopartite begomovirus *Ageratum yellow vein virus*, was shown to be maintained in plants by the NW bipartite begomovirus *Tomato golden mosaic virus* and the curtovirus (family *Geminiviridae*, genus *Curtovirus*) *Beet curly top virus* (BCTV). When maintained in plants by BCTV, AYVSGA co-insect transmitted by the leafhopper vector of BCTV, showing the vector of the alphasatellite to depend upon the vector specificity of the helper virus. The same work also showed AYVSGA not to be maintained in plants by the mastrevirus (family *Geminiviridae*, genus *Mastrevirus*) Chickpea chlorotic dwarf virus (CpCDV; earlier known as Bean yellow dwarf virus), possibly due to packaging constraints; the genome of CpCDV is significantly smaller than the genomes of the begomoviruses by which it is maintained.

Pathogenesis

The precise impact of alphasatellites on nanovirus and geminivirus infections remains unclear. For some nanovirus infections the presence of nanoalphasatellites has been shown to reduce nanovirus infectivity. This suggests that there is competition between the nanoalphasatellite and the *bona fide* nanovirus genomic DNAs for factors required for replication, systemic movement and/or encapsidation. For geminivirus infections the presence of geminialphasatellites has been shown to result in either attenuated or exacerbated symptoms. For infections with attenuated symptoms the DNA titer of either the virus genome or the associated betasatellite were found to be reduced in comparison to plants not inoculated with the alphasatellite.

The Rep proteins encoded by the geminialphasatellites *Gossypium darwinii* *symptomless alphasatellite* and *Gossypium mustelinum* *symptomless alphasatellite* suppress post-transcriptional gene silencing (PTGS), whereas those encoded by various other geminialphasatellites are suppressors of transcriptional gene silencing (TGS). This suggests that some, if not all, alphasatellites assist the helper virus in overcoming (suppressing) host resistance based on RNA interference ([Table 1](#)).

Nomenclature

CP Coat protein

dsRNA Double stranded RNA

ORF Open reading frame

RdRp RNA-dependent RNA polymerase

RT-LAMP Reverse transcription loop-mediated isothermal amplification

RT-PCR Reverse transcription polymerase chain reaction

Glossary

Bicistronic Nucleic acid that codes for two proteins.

Nucleoprotein Protein protecting the genomic RNA of negative sense RNA viruses.

Ribosomal frameshift Translation strategy, quite widespread in viruses, that allows for the expression of two partially overlapping, non-in-frame ORFs in a single round of translation involving ribosome slipping by one base in either the 5' or 3' directions.

Classification

The family *Amalgaviridae*, part of the realm *Riboviria*, was recognized by the International Committee on Taxonomy of Viruses (ICTV) in 2014. The family includes viruses infecting plants and fungi (yeasts) with a non-segmented, bicistronic dsRNA genome of 3.1–3.5 kbp and is currently composed of two genera: *Amalgavirus* and *Zybavirus*. The genus *Amalgavirus* contains 9 officially recognized species while the genus *Zybavirus* has only one species. The type species for genus *Amalgavirus* is *Southern tomato virus*, and the type species for the genus *Zybavirus* is *Zygosaccharomyces bailii virus Z* (**Table 1**). There are also another 27 possible members of the family for which sequences are available and phylogenetic studies indicate that at least 12 of them could be classified in the genus *Amalgavirus* while one (*Antonospora locustae virus 1*, AnLoV-1) could be classified either in the genus *Zybavirus* or represent a completely new genus in the family (**Fig. 1**).

Virion Structure

Virus particles have never been observed for plant amalgaviruses under the electron microscope, but antibodies against the putative product of ORF1, with possible role of the viral CP, reacted with amorphous bodies in infected plants. Biochemical analysis points to protection of the genome by a protein. *In silico* analyses indicate that the putative CP of amalgaviruses is homologous to the nucleoprotein of animal and plant-infecting negative stranded RNA viruses suggesting the possibility of filamentous particles instead of the hypothesized spherical ones. The spherical particle hypothesis is based on *Zygosaccharomyces bailii virus Z* (ZbV-Z), where virus-like particles were purified from yeast. Notwithstanding, purification was performed using an isolate co-infected with a totivirus which is known to form spherical particles.

Genome

The genome of amalgaviruses is comprised of a single double stranded RNA (dsRNA) molecule of ~3.5 kbp (viruses in the genus *Amalgavirus*) or ~3.1 kbp in size (*Zygosaccharomyces bailii virus Z*, sole member of the genus *Zygovirus*). All viruses in the family code for two proteins (**Fig. 2**). The 5' proximal protein is presumed to be the CP of the virus. As noted above, the protein is homologous to the nucleoprotein of animal and plant-infecting negative strand viruses. The second protein, encoded by ORF2, is predicted to be expressed via a programmed +1 ribosomal frameshift and contains RdRp motifs most similar to those found in members of the family *Partitiviridae*. Putative +1 ribosomal frameshifting motif, UUU_CGN, present in all but two plant amalgaviruses was identified recently by extensive *in silico* analyses. Phylogenetic analyses have shown that RdRp of amalgaviruses is evolutionarily closer to that of partitiviruses than to counterparts expressed by members of the family *Totiviridae*. Overall, the genome appears to be an amalgam of the monopartite family *Totiviridae* and the multipartite family *Partitiviridae*.

Life Cycle

Little is known about the life cycle of amalgaviruses. The plant-infecting members of the family are not mechanically, nor graft-transmissible. They are very efficiently transmitted through seed, reaching 100% transmission in the case of southern tomato virus (STV) and blueberry latent virus (BLV). ZbV-Z can be transmitted to other yeast species.

Epidemiology

Given the lack of a identifiable movement protein it is hypothesized that the plant-infecting members of the family move within their hosts only during cell division. No symptoms have been observed in hosts infected with any member of the genus *Amalgavirus* although there are reports of STV having a mutualistic interaction with tomato or affecting the expression of tomato miRNAs. The effect of ZbV-Z on its hosts remains unknown.

Pathogenesis

None known.

Fig. 1 Phylogenetic tree of recognized (red font) and putative members (black) of the family *Amalgaviridae*. The tree was reconstructed on amino acid sequences of viral RdRPs initially aligned with MUSCLE (v3.8.31) and curated by Gblocks (v0.91b) in order to remove ambiguous regions. The phylogenetic tree was reconstructed with the maximum likelihood method implemented in the PhyML program (v3.1/3.0 aLRT), applying LG + G substitution model, estimated to be best-fit for this dataset. Reliability for internal branch was assessed using the aLRT test (SH-Like). The tree was edited and visualized with FigTree (v1.44). Complete names of viruses used in the analyses are: *Allium cepa* amalgavirus 1 (AcAV1; BK010347), *Allium cepa* amalgavirus 2 (AcAV2; BK010348), *Anthoxanthum odoratum* amalgavirus 1 (AoAV1; BK010356), *Antoniospora locustae* virus 1 (AnloV1; KX525322), *blueberry latent virus* (BILV; HM029246), *Camellia oleifera* amalgavirus 1 (CoAV1; BK010409), *Capsicum annuum* amalgavirus 1 (CaAV1; BK010407), *Cleome droserifolia* amalgavirus 1 (CIDAV1; BK010408), *Erigeron breviscapus* amalgavirus 1 (EbAV1; BK010410), *Erigeron breviscapus* amalgavirus 2 (EbAV2; BK010411), *Festuca pratensis* amalgavirus 1 (FpAV1; BK010412), *Festuca pratensis* amalgavirus 2 (FpAV2; BK010413), *Medicago sativa* amalgavirus 1 (MsAV1; BK010406), *Neurachne minor* latent virus (NmLV1; MF325033), *Phalaenopsis equestris* amalgavirus 1 (PeAV1; BK010405), *rhododendron virus A* (RhVA; HQ128706), *Salvia hispanica* RNA virus 1 (ShRV1; MH988691), *southern tomato virus* (STV; EF442780), *spinach amalgavirus 1* (SpAV1; KY695011), *Vicia cryptic virus M* (VCVM; EU371896), *Zostera marina* amalgavirus 1 (ZmAV1; KY783316), *Zostera marina* amalgavirus 2 (ZmAV2; KY783317), *Zygosaccharomyces bailii* virus Z (ZbV-Z; KU200450). Amino acid sequences of RdRPs of *Nigrospora oryzae* unassigned RNA virus 1 (NoURV1; KT258976) and *Ustilagoidea vires* nonsegmented virus 1 (UvNV1; KJ605397) were used as outgroups. The two genera of the family, *Amalgavirus* and *Zybavirus*, indicated.

Fig. 2 Genome depiction and putative protein products of Southern tomato virus (STV), the type member of the genus *Amalgavirus*. The two open reading frames are coded in the same strand and translate to the putative coat protein (red block) and its fusion with the RNA dependent RNA polymerase (RdRp; blue).

Diagnosis

There are many protocols developed for the type species of the genus *Amalgavirus*, southern tomato virus, which include RT-PCR, quantitative RT-PCR, molecular hybridization and RT-LAMP. The other viruses in the family are primarily detected by virus-specific RT-PCR.

Treatment

Virus-elimination protocols such as thermo-/chemo-/cryotherapy have not been reported for any amalgavirus. Yeast can be cured from ZbV-Z using cycloheximide or elevated temperatures.

Prevention

The best prevention approach for all plant viruses including amalgaviruses is to start with clean propagative materials. Independent of true seed or clonal propagation, mother plants should be tested free of the respective amalgavirus.

Glossary

Discontinuity Gap in the DNA strand.
Endogenous viral element Viral DNA integrated in the nuclear genome of the host organism and inherited from parents like any normal cellular gene.
Minichromosome Viral DNA wrapped around histone proteins in the nucleus.

Reverse transcription Use of an RNA template to direct synthesis of a complementary strand of DNA.
Virion The virus particle, consisting of a DNA genome surrounded by a protein shell and constituting the infective form of the virus.
Viroplasms Virus factories.

Introduction

The genus *Badnavirus* is a group of double-stranded (ds) DNA viruses with bacilliform particles in the family *Caulimoviridae*. They are referred to as 'reverse-transcribing viruses' as they produce a single-stranded RNA replicative intermediate, which acts as the template for reverse transcription back to dsDNA. Badnaviruses have been mainly identified in tropical regions and they have an extremely wide host range: a significant number of badnaviruses are pathogens of crop plants, such as banana, citrus, cacao, fig, grapevine, pepper, pineapple, raspberry, sugarcane, and sweet-potato, but many more are been found in ornamental plants such as bougainvillea, hibiscus, kalanchoe, lucky bamboo, pelargonium and wisteria. So far badnaviruses have been shown to be transmitted by two types of insect vector, aphids and mealybugs. A total of 68 species are currently recognized by the ICTV, and in addition there are six tentative species in the genus. There is also evidence in the form of endogenous viral elements (viral DNA that is integrated in the plant genome) that many more plant species have been exposed to badnaviruses throughout their evolution. The molecular species demarcation criteria of 80% identity of nucleotide sequences has been set 20 years ago, and now that so many more badnavirus complete genome sequences are available, this demarcation threshold should be revisited.

Classification

The genus *Badnavirus*, typified by *Commelina yellow mottle virus*, currently contains 68 officially recognized species and six tentative virus species (Table 1), making it the largest of all genera in the family *Caulimoviridae*. All members of the family *Caulimoviridae* have the conserved core of replication and structural proteins found within the order *Ortervirales*, called the gag-pol, which are names originating from the retrovirus literature and are abbreviations of 'group antigens' and 'polymerase', respectively. In badnaviruses, the gag gene encodes the major capsid protein (CP) and the pol gene, the replication-associated enzymes, namely the aspartic protease and reverse transcriptase/ribonuclease H1 proteins. The caulimoviruses are sometimes referred to as 'plant-infecting pararetroviruses' but the term 'pararetrovirus' has no taxonomic standing and is purely a descriptive term used to describe reverse-transcribing viruses that encapsidate a double-stranded DNA (dsDNA) form of the viral genome rather than single-stranded RNA (ssRNA) in the case of retroviruses. Caulimoviruses are united with all members of the *Ortervirales* by alternating between double-stranded DNA and single-stranded RNA during the replication cycle through cycles of transcription and reverse transcription. The RNA intermediate in the replication cycle is termed the pregenomic (pg) RNA. The key characteristic that differentiates the genus *Badnavirus* from all other members of the family *Caulimoviridae* is genome organization.

The criteria for demarcation of different badnavirus species is less than 80% nucleotide identity within the reverse transcriptase and ribonuclease H1 coding regions of ORF3, differences in host range and vector specificities. Evolutionary relationships within the genus are illustrated in Fig. 1.

Table 1 List of species, tentative species and unassigned viruses in the genus *Badnavirus*, family *Caulimoviridae*. Their acronym, accession # of an exemplar, natural hosts, geographical distribution, and their capacity to be endogenous are also indicated

^aOnly a partial genome sequence is available for *Schefflera ringspot virus* (MH475920) and this sequence is 99.1 identical to the genome sequence of *Ivy ringspot-associated virus* (MN850490), suggesting the two species are synonymous.

Fig. 1 Phylogram depicting relationships within the genus *Badnavirus*, based on a maximum likelihood analysis of a *pol* gene sequence alignment using the IQ-TREE web server. The *pol* gene sequence alignment of approved badnavirus species was downloaded from the ICTV *Caulimoviridae* Resources Page and amended with sequences of tentative badnavirus species that are available on GenBank. GenBank accession codes and virus acronyms (see [Table 1](#)) are provided at the tips of the branches; rice tungro bacilliform (RTBV) is the outgroup. Ultrafast bootstrap support values (%) from 1000 replicates are shown in the nodes of the branches (only values > 70% are shown).

Fig. 2 Virions of Banana streak IM virus (BSIMV), negatively stained with 1% ammonium molybdate pH 7. Micrograph courtesy of K.S. Crew.

Virion Structure

Virions are bacilliform with parallel sides and rounded ends, and modal dimensions of 30 nm × 130 nm (Fig. 1). However, virions that are two to three times this modal length are sometimes observed, and these contain non-covalently bonded concatemers of viral genomic DNA that are up to four monomeric units in length. Two types of virion are observed in mulberry plants infected by Mulberry badnavirus 1 (MBV1), one that has normal dimensions and a second that is thinner (*c.* 20 nm diameter) and has a looser capsid structure. These aberrant virions contain a shorter form of the MBV1 genome.

The main structural protein of the virion is the capsid protein (CP), while a second protein, the virion-associated protein (VAP), is thought to decorate the surface of the virion by occupying the pores between the capsomers. At the C-terminus of the VAP, there is a proline-rich region that binds to double-stranded DNA in a sequence non-specific manner, and putatively interacts with the encapsidated DNA. Conversely, the N-terminus of the VAP is thought to be surface-exposed and contains a coiled-coil motif that could interact with other viral, host or insect proteins to mediate functions in the virus' life cycle such as cell-to-cell movement and vector transmission (Fig. 2).

Genome

The encapsidated form of the badnaviral genome is a non-covalently closed dsDNA molecule of 7.0–9.3 kbp. There are discontinuities in each strand of DNA, which arise as a consequence of synthesis of the DNA strands by reverse transcription. Synthesis of the negative strand of DNA is primed by a cytosolic initiator methionine tRNA ($tRNA^{met}$), and the discontinuity on this strand is adjacent to the 3' end of the homology to the $tRNA^{met}$. On the positive strand, the discontinuity is located within a polypurine-rich region within ORF3. By convention, position 1 of the genome is designated the first nucleotide of the $tRNA^{met}$ binding motif (5' T₁GGTATCAG.... 3') on the positive strand.

The majority of badnavirus genomes have three conserved open reading frames (ORFs), which are in different translational reading frames (Fig. 3). For the most part, the start codons for these ORFs are AUG but for some species, non-conventional start codons are utilized, particularly at the beginning of ORF1 (e.g., CUG for BSMYV ORF1). Other ORFs have been described but these are not found in all species and evidence that these ORFs are translated is lacking. It is typical for the stop codons of ORFs 1 and 2 to overlap the start codons of the succeeding ORFs. ORF1 encodes a small protein of *c.* 21–25 kDa that has no assigned function but is recognizable through the presence of a conserved domain, pfam07028. ORF2 also encodes a small protein of *c.* 15 kDa, the VAP. ORF3 encodes a large polyprotein of *c.* 197–232 kDa, with conserved movement protein (MP), capsid protein (CP) and nucleocapsid, aspartic protease, reverse transcriptase and RNase H domains in that order. All domains in the polyprotein bar the MP have strong sequence conservation at primary and secondary structural levels with paralogous proteins of retroviruses and long terminal repeat retrotransposons, and are classified in the same protein families.

Two variants of the typical badnavirus genome organization are known. MBV1 has a genome sequence with one long ORF, which appears to be the equivalent of a fusion of ORFs 1 and 3 in other badnaviruses based on the arrangement of conserved domains. The genome sequence of sweet potato pakakuy virus (SPPV), which contains four ORFs, represents yet another permutation of the typical badnavirus genome. ORF3 encodes the MP and CP, while ORF4 encodes the aspartic protease and reverse transcriptase/ribonuclease H1 proteins. Hence for SPPV, ORF3 in other badnaviruses is split in two.

The intergenic region in the genome between the end of ORF3 and the beginning of ORF1 in the typical badnavirus genome is long and contains transcription regulatory motifs. Between the end of ORF3 and the $tRNA^{met}$ motif, there is the equivalent of the cauliflower mosaic virus 35S promoter, identifiable by the presence of a TATA box. Due to prospects of using the badnavirus promoter for genetic engineering of plants, there has been considerable work done to identify the minimal promoter sequences and to identify cis-acting elements that control the specificity of tissue expression. Downstream of the promoter is a polyadenylation signal but only a small percentage of the RNA transcripts have a poly(A) tail.

Fig. 3 Genome map for *Commelina* yellow mottle virus (ComYMV), type species of the genus *Badnavirus*. The black circle represents the genomic DNA, the purple circle is the pregenomic RNA and the gray curved boxes are the open reading frames. Marked on the genomic DNA are the positions of the TATA box (black diamond), polyadenylation signal (black arrow) and tRNA^{met}-binding site (black clover). The blue, green, red, orange and yellow curved boxes represent the movement protein, capsid protein, aspartic protease, reverse transcriptase and RNaseH domains on ORF 3, respectively.

Life Cycle

The replication cycle of badnaviruses has not been investigated to any great extent, and most knowledge is based on extrapolation from model plant viruses such as cauliflower mosaic virus (CaMV), and to a lesser extent, rice tungro bacilliform virus (RTBV).

Following entry of the badnavirus virion into the cell, the encapsidated viral DNA needs to be transported to the nucleus for replication to begin. A putative nuclear localization signal (NLS) is present in the basic, intrinsically disordered region of the NC domain of the CP. For RTBV, this NLS facilitates interaction between the CP and importin α but as the NLS is within the mature virion, is unlikely to play a role in docking of the virion to the nuclear pore but rather entry of the genomic DNA after either partial or complete virion decapsidation. There are two major CP isoforms that vary in length of the acidic N-terminus of the protein. It is not clear whether this variation in length is due to the presence of alternative aspartic protease cleavage sites or is a consequence of targeted degradation of the protein. With CaMV, the extended N-terminus inhibits nuclear targeting of the protein, ensuring that it is localized within the cytoplasm where virion assembly occurs.

Once the genomic DNA enters the nucleus, it is assumed that replication follows the pathway of CaMV, whereby the discontinuities in the genomic DNA are repaired to form a covalently closed circle, and the DNA then associates with histone proteins and RNA polymerase II to form transcriptionally active complexes called minichromosomes. A single, terminally redundant, slightly greater than genome-length RNA transcript is produced called the pregenomic RNA (pgRNA), and there is no evidence of subgenomic or spliced RNA transcripts. Following the replication model proposed for CaMV, it is thought that the RNA polymerase II enzyme begins transcription, ignores the polyadenylation signal on the first pass, continues transcribing around the circle and drops off the DNA template when it reaches the polyadenylation signal for the second time. Hence, the region between the transcription start site and the polyadenylation signal is duplicated at the 5' and 3' ends of the pgRNA.

It has been a mystery as to where in the cell, virion assembly occurs but recent studies suggest that badnaviruses produce viroplasm (virus factories) that are equivalent in function to those of CaMV but clearly different in composition because badnaviruses lack the major viroplasm matrix protein produced by caulimoviruses. These putative viroplasms have a characteristic structure comprising an undifferentiated core, an encircling lacuna where reverse transcription may occur, and an outside ring of differentiating virions. A gap is present in the outside ring, allowing the import of newly synthesized viral proteins from the surrounding ribosomes.

The pgRNA, which also acts as the messenger RNA, is polycistronic and the downstream ORFs are likely translated by a leaky ribosome scanning mechanism, whereby the start codons of ORFs 1 and 2 are in sub-optimal initiation contexts and are bypassed by the ribosome on a fraction of occasions in favor of the next downstream start codon. Consistent with this translation mechanism, internal AUG codons are rare to absent in ORFs 1 and 2. The 5' leader sequence of the pgRNA is long and folds into a stable hairpin structure, which is immediately preceded by a short upstream ORF (uORF). It is proposed that translation initiates at the start of the uORF and the ribosome then shunts across the hairpin structure to a landing site near the beginning of ORF1, where translation recommences. The uORF could regulate sorting of the ribosomes between the three ORFs to maintain balanced production of the different proteins.

The large polyprotein encoded by ORF3 must be post-translationally processed to release each individual component protein. Within the polyprotein is an aspartic protease, which belongs to the retrovirus aspartic protease family (pfam00077) and has a highly conserved active site (motif Asp-Ser/Thr-Gly). It is hypothesized that the aspartic protease autocleaves and then processes other proteins in the polyprotein. Based on studies with retroviruses, the active form of the protease is likely to be a β homodimer. Substrate sites for the enzyme are not strictly conserved at the amino acid sequence level and cleavage sites must be empirically determined. No badnaviral aspartic protease has been biochemically characterized and there has only been one attempt to map a cleavage site, at the N-terminus of the BSMYV capsid protein.

The final step in the badnavirus replication cycle, reverse transcription, is thought to follow the general model for CaMV. The (–) strand of DNA is first synthesized using the pgRNA as the template, the virus-encoded reverse transcriptase as catalyst and a tRNA^{met} molecule to prime the reaction. When the reverse transcriptase reaches the 5' end of the pgRNA, the nascent end of the DNA melts away from the RNA and anneals to the identical stretch of sequence at the 3' end of the pgRNA. Reverse transcription then continues around the circle until the original tRNA^{met}-binding site is encountered. At some point, the pgRNA and tRNA^{met} molecule must be removed, presumably through the action of the virus-encoded RNaseH enzyme. Synthesis of the (+) strand of DNA then begins, presumably using a host-encoded DNA polymerase and a primer that has yet to be characterized.

Transmission electron microscopy studies suggest that badnaviruses are trafficked between cells as whole virions and this is enabled by the formation of a tubule that displaces the contents of the plasmodesmum and increases its size exclusion limit. Badnaviruses produce an example of the 30K superfamily of viral MP, which is most closely related to those produced by nepo- and ideoviruses.

Epidemiology

The epidemiology of many of the badnaviruses is poorly understood, and most knowledge derives from the study of a small number of diseases with the largest economic impacts, such as cacao swollen shoot and banana streak disease.

The majority of badnavirus species are transmitted by mealybugs (family Pseudococcidae), which are most abundant in warm, moist climates or in greenhouses. Mealybugs inhabit protected sites on the plant such as the underside of plant leaves and stems, in leaf axils and the underneath leaf sheaths, and on the roots, and hence their presence may be overlooked. Where known, the virus-vector specificity of mealybug transmission is weak, although there is very little data on this topic due to the difficulties of rearing mealybugs and doing controlled transmission experiments. At least fourteen species of mealybug are capable of transmitting the cacao swollen shoot complex of viruses, although three species are considered the most important vectors, namely *Formicococcus njalensis*, *Planococcus citri* and *Ferrisia virgata*.

The most mobile growth stages of the mealybug are the first and second instars of nymph, and these are also known as 'crawlers'. Crawlers move over most parts of the plant, whereas older nymphs and adults will retreat to more protected positions on the plant. Transmission of badnaviruses can occur when either the crawlers actively cross leaf bridges between plants or are passively transported by the wind or carried by attendant ants. Ants have a strong mutualistic relationship with mealybugs, as they feed on their honeydew secretions and in turn, provide protection from parasites and predators and improve hygiene by cleaning up waste products. Mealybugs can be indirectly controlled by reducing ant populations using insecticides.

The second most important group of badnavirus vectors is aphids, and again these transmit the viruses in the semi-persistent manner. Only five species of badnavirus are known to be transmitted by aphids, namely chestnut mosaic virus (ChMV), gooseberry vein-banding associated virus (GVbAV), Rubus yellow net virus (RYNV), Spirea yellow leaf spot virus (SYLSV) and grapevine vein clearing virus (GVCV). All four viruses are closely related, and all originate from temperate regions of the Northern Hemisphere. Evolution of this novel virus-vector relationship may reflect the greater abundance of aphids in higher latitudes of Eurasia and North America relative to mealybugs.

The only other type of insect that can vector badnaviruses is the black pepper lace bug (*Diconocoris distanti*), which together with the citrus mealybug (*Planococcus citri*), is reported to transmit Piper yellow mottle virus (PYMoV); but this finding does need independent verification.

True seed transmission has been reported for several badnavirus species including PYMoV in black pepper, Kalanchoe top spotting virus (KTSV) in *Kalanchoë blossfeldiana*, SPPV in *Ipomoea batatas* and an unidentified species of taro bacilliform virus in *Colocasia esculenta*. A report that BSMYV is seed-transmitted in banana is ambiguous as there is the possibility that the infections in seedlings originated from activation of endogenous badnaviral elements. While seed transmission of many badnaviruses is theoretically possible, it is likely to be epidemiological insignificant as many of the host species are vegetatively propagated.

Where known, most badnaviruses have narrow host ranges in nature and alternative hosts are unlikely to play an important role in the virus epidemics but there are important exceptions. It is well documented that the indigenous rainforest trees in West Africa are the origins of the badnaviruses associated with cacao swollen shoot disease. When the rainforest was cleared for cropping, some trees were left to provide shade for the cacao plants, and these acted as primary sources of inoculum for the epidemics. The most important alternative host trees for cacao swollen shoot in Ghana are *Cola gigentia*, *Cola chlamydanthia* and *Ceiba pentandra*, all from the same Malvaceae family as *Theobroma cacao*. However, pockets of older, infected cacao trees in the same or neighboring plantations are now the most important sources of inoculum and disease control is dependent on operation of an effective roguing program.

Other examples of cross-species transmission of badnaviruses include banana streak CA virus, which as the name suggests, was first described from banana but appears to be more common in sugarcane. These two crops grow on the same types of soil, and often on the same or neighboring farms, and it is thought that infections in banana originate from nearby sugarcane plants. Canna yellow mottle virus (CaYMV), a virus that is ubiquitous in ornamental canna plants in the tropics, is responsible for diseases in betel nut (*Piper betel*) in Pakistan and ornamental ginger (*Alpinia purpurata*) in Hawaii. Finally, wild members of the Vitaceae family such as *Vitis rupestris* and *Ampelopsis cordata* are important alternative hosts of GVCV, which causes grapevine decline in the American Midwest. The frequency of cross-species transmission of these viruses is unknown but does not need to be common for the infections to proliferate as all crops are vegetatively propagated.

Clinical Features

Badnaviruses typically produce chlorotic streaks, mild mottles and sometimes ringspot patterns on the leaves of monocots, and mottle and mosaic patterns, vein clearing and ring spots on the leaves of dicots (Fig. 4). Plants affected by cacao swollen shoot disease have distinctive protuberances on the stems, caused by proliferation of the xylem, phloem and cortex cells.

Plants infected by badnaviruses may be asymptomatic or symptoms sporadic in occurrence, as best documented with the various species of the banana streak disease complex (BSD). The factors triggering symptom expression in banana are poorly understood but there is a clear trend of symptom severity increasing with maturity of the plant, reaching a maximum at about the time of bunch initiation. For BSD, virus titer is also positively correlated with symptom severity but infection often leads to cell death, causing the chlorotic streaks to turn necrotic, and virus titer to decline again.

Cabernet Franc infected by Grapevine vein clearing virus (GVCV) (photograph courtesy of W. Qiu); E, *Citrus x sinensis* infected by citrus yellow mosaic virus (CiYMV) (photograph courtesy of V.S. Baranwal); F, *Aucuba japonica* infected by Aucuba ringspot virus (AuRSV) (photograph courtesy of A. Uke).

Pathogenesis

There is scant information on how badnaviruses cause disease. The tissue tropism of badnaviruses is variable and dependent on the virus in question. Rubus yellow net virus infects all cell types of the raspberry leaf including the epidermis but is most common in the phloem companion cells. BSMYV most commonly occurs in the palisade and spongy mesophyll cells and rarely in the epidermal cells of the banana leaf. Cacao swollen shoot Togo B virus (CSSTBV) appears to be mainly vascular-limited, with most virions observed in the phloem companion cells and far less commonly in the xylem parenchyma cells.

Cytopathological studies suggest that badnaviruses trigger cell apoptosis although further studies are required to confirm these observations. Older infected cells exhibit severe plasmolysis, accumulate vacuoles, the chloroplasts become deformed, starch granules aggregate and the cells eventually lose all contents. The putative viroplasms can reach relatively large diameters and are easily visible by light microscopy using stains such as periodic acid-Schiff-toluidine blue.

One peculiar aspect of the biology of badnaviruses, particularly among plant-infecting viruses, is that new infections can arise following activation of viral sequences that are integrated in the nuclear genome of the host plant. These integrated sequences are commonly referred to as endogenous viral elements. Badnaviruses do not actively integrate into their host genome as do retroviruses but it is thought that the viral DNA is captured as a type of filler sequence during non-homologous or microhomology-mediated end-joining repair of double-stranded DNA breaks in the chromosomal DNA. Integration of viral DNA is part of a broader phenomenon of horizontal gene transfer involving all types of DNA, such as that from the plastid genomes.

The problem of endogenous badnaviral elements causing new infections was discovered in a quest to understand why new hybrid bananas generated by banana breeding programs around the world became infected with banana streak OL virus (BSOLV), despite the fact that the parent plants used to create the hybrids were healthy. A locus was discovered in one parent, cv. 'Obino l'Ewai' (*Musa* AAB group), which contains the complete genome sequence of BSOLV but divided in two fragments separated by a large scrambled region of fragments of non-contiguous and sometimes inverted viral sequence. An activation model was proposed involving two homologous recombinations, the first to excise the scrambled region and the second to join either end of the locus to form a circular, transcriptionally active form of the genome. This locus has now been better characterized and shown to be diallelic, with only one allele being infective. Activation is not spontaneous but triggered by external factors such as tissue culture propagation and interspecific hybridization. It is hypothesized that in a normal state, the endogenous badnaviral elements are transcriptionally silenced but certain stresses cause the transient release of this silencing.

The phenomenon of activation of endogenous badnaviral elements has now been extended to at least two more badnaviruses, banana streak GF virus (BSGFV) and banana streak IM virus (BSIMV) and as with BSOLV, activation involves recombinations to reconstitute complete viral genomes. All aforementioned replication-competent endogenous banana streak viruses are linked to the B genome of banana, which derives from *Musa balbisiana*. The A genome of banana (from *Musa acuminata*) also contains endogenous badnaviral elements but these are derived from different ancestral badnavirus species and all are regarded as being replication-defective due to the accumulation of mutations, rearrangements and deletions.

Endogenous badnaviral elements have now been detected in a broad range of plant species, both monocots and dicots. While it is not particularly surprising that badnaviral DNA is captured in the host genome, a more perplexing question is why the DNA has become fixed in the genome and has persisted for hundreds of thousands, even millions of years. It is generally assumed that the endogenous badnaviral elements confer a selective advantage to the plant, such as imparting resistance against the cognate infectious virus through activation of RNAi defense pathways. However, it is likely that the endogenous badnaviral elements could also help shape the transcriptome by, for example, contributing novel promoter elements or being a source of small non-coding RNAs. Furthermore, it is conceivable that badnaviral proteins are generated that may have been coopted for some other function in normal plant metabolism.

Diagnosis

Badnaviruses vary considerably in the difficulty of diagnosis, depending on the presence of endogenous badnaviral elements in the plant, as there is a need to distinguish these from encapsidated (exogenous) viral DNA. This problem is best exemplified by the various species of banana streak disease. When describing a new species of badnavirus, it is also essential to demonstrate that the DNA sequence derives from exogenous viral DNA.

The nuclear genome of cultivated banana contains multiple copies of endogenous badnaviral DNA, representing a large range of ancestral virus species. However, dessert banana such as the Cavendish subgroup of cultivars have an AAA genome, which is devoid of endogenous forms of Banana streak OL virus (BSOLV), Banana streak GF virus (BSGFV), Banana streak IM virus (BSIMV) and Banana streak MY virus (BSMYV). Hence, conventional PCR using species-specific PCR primers and total plant DNA extracts can be used for diagnosis. However, for hybrid plantain or dessert banana cultivars with AAB or ABB genotypes, conventional PCR cannot be used because of the problem of endogenous viral DNA giving false positive diagnostic results.

Two diagnostic technologies are routinely used to distinguish endogenous from exogenous viral DNA, these being immunocapture PCR and rolling circle amplification. The first step of immunocapture PCR is to trap virions on the sides of a PCR tube, and then to wash away other cellular components including plant nucleic acids. While this step does enrich for virions, plant DNA can bind directly to the tube wall and precautions need to be taken to prevent this from happening. Non-specific binding of DNA to the tube wall is a much slower process than the antibody-virion interaction, and limiting the immunocapture step to 3 h at room temperature helps prevent amplification of endogenous badnaviral elements. To alert the diagnostician of direct binding of

plant DNA, duplex PCRs can be done using primers against repetitive DNA sequences in the plant such as microsatellites. Another option is to do a DNase I digestion step after the immunocapture step, as the capsid shell protects the encapsidated DNA from nuclease degradation. One of the major constraints to the wider adoption of immunocapture PCR for diagnosis is the lack of availability of antibodies against many of the viruses but use of anti-peptide antibodies shows promise for rapidly resolving this problem. Some crop species such as banana, sugarcane and yam, are infected by a broad diversity of badnaviruses and universal badnavirus-group primers have been designed to cover most combinations of virus species.

Rolling circle amplification (RCA) using *Phi29* DNA polymerase is a very useful technique for characterizing badnaviral genomes and for the most part, the selected method has been to use a commercial RCA kit (TempliPhi™) that has been spiked with a mixture of degenerate and specific badnavirus primers to increase the sensitivity of detection. It is only the minichromosomal fraction of viral DNA that is amplified by RCA, as the discontinuities present in the encapsidated DNA cannot be bridged by the DNA polymerase. TempliPhi™ is a sequence independent amplification method, as DNA polymerization is primed with random hexamers, and this has sometimes created problems with interpreting results, as circular plant plastid DNA sequences may also be amplified. However, major improvements to the specificity of amplification by RCA have been made by formulating reaction mixtures from individual components, replacing the random hexamers with a panel of degenerate badnavirus primers, and optimizing amplification temperatures.

Prevention

The two foundations of badnavirus prevention are the use of virus-indexed planting material and the operation of disease roguing programs. Virus indexing is particularly important for crops such as banana, which are propagated by tissue culture and a single meristem can give rise to 500 progeny plants. For chronically-infected, vegetatively propagated plants, somatic embryogenesis and meristem-tip culture can be used to eliminate virus, and the success of the technique is enhanced by combining with chemotherapy. The use of insecticides to control mealybug vectors is generally considered to be ineffective due to the waxy, water-repellant coatings on the insect and the cryptic places where the insects feed but there may be a place for systemic insecticides in a management program.

A problem exists with hybrid (A x B genome) bananas and plantains as the practice of tissue culture in itself provides the trigger for activation of endogenous badnaviral elements and this is particularly a concern for the banana breeding programs as embryo rescue is integral to the breeding process. PCR diagnostic assays have now been developed to screen for replication-competent alleles of the endogenous banana streak viruses, and use of these diagnostic assays allows identification of cultivars that are particularly prone to becoming infected when propagated by tissue culture. The long term solution to the issue of endogenous badnaviral elements causing infection is to create plants that are devoid of replication-competent endogenous virus alleles by conventional breeding techniques or by inactivating these alleles using gene-editing techniques such as CRISPR/Cas9.

Cacao swollen shoot is undoubtedly the most economically important disease caused by badnaviruses, and no plant disease resistance is available and therefore the primary control strategy has been roguing, resulting in the destruction of over 200 million trees in Ghana since 1946. Mild strain cross protection does not protect plants from superinfection by virulent strains but does slow the rate of spread by nearly half. Oil palm and citrus barriers can also be used to slow the reintroduction of cacao swollen shoot into newly planted, healthy crops and at the same time provide an alternative source of income for the farmers.

This is an update J.E. Thomas, Banana Bunchy Top Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00636-1](https://doi.org/10.1016/B978-012374410-4.00636-1).

Glossary

Cell-cycle link protein A plant virus protein which most probably subverts the cell cycle control of the host, forcing cells into DNA synthesis or S phase favorable to viral replication.

Circulative transmission Mode of transmission whereby the virus is internally borne in the insect vector but does not

replicate there. It is characterized by a latent period before which transmission cannot occur, and by retention of infectivity by the vector for a period of at least weeks.

Nuclear shuttle protein A virus-encoded protein that transports the viral single-stranded DNA, as a complex with the viral movement protein, to and from its site of replication in the nucleus and into adjacent cells.

Introduction

Banana bunchy top disease is the most economically important virus disease of banana and plantain (*Musa* spp.) worldwide, due to its devastating effect on crop yield, and the importance of banana and plantain as both a staple food and a major export commodity in much of the developing world. The causal agent is Banana bunchy top virus (BBTV), which has a multipartite circular ssDNA genome, encapsidated in small isometric virions, and is transmitted by the banana aphid, *Pentalonia nigronervosa*. Edible bananas are derived from wild seeded progenitors including predominantly subspecies of *M. acuminata* and *M. balbisiana*, which have a center of origin in South and South-East Asian-Australasian region. It is likely that BBTV and the aphid vector also originated within this area.

Taxonomy, Phylogeny, and Evolution

BBTV is a member of the genus *Babuvirus*, in the family *Nanoviridae*. Recently, two new virus species have been identified which are clearly distinct members of the genus *Babuvirus* (Fig. 1). *Abaca bunchy top virus*, which also infects *Musa* in South-East Asia, and *Cardamom bushy dwarf virus* causing Foorkey disease of cardamom in India, both have homologous components for all six genome components of BBTV. Additional species in this family are classified in the genus *Nanovirus*, and include *Faba bean necrotic yellows virus*, *Milk vetch dwarf virus* *Subterranean clover stunt virus*, *Black medic leaf roll virus*, *Faba bean necrotic stunt virus*, *Faba bean yellow leaf virus*, *Pea necrotic yellow dwarf virus* and *Pea yellow stunt virus*. Members of this family are phylogenetically related and share a similar particle morphology and multi-component circular, ssDNA genome. However, members of the two genera are not serologically related. Although both genera possess five components vital to replication and spread in common, some additional components present in one genus do not have a homologous component in the other genus. However, some of these components encode proteins on unknown function, and these unrelated proteins may share similar functions.

Fig. 1 Phylogenetic tree based on the amino acid sequences of babuvirus Rep proteins, using the nanovirus *Faba bean necrotic yellows virus* as an outgroup. The South-East Asian and Pacific/Indian Ocean subgroups of BBTV, with representative isolates, are circled in blue and red, respectively.

Fig. 2 Electron micrograph of BBTV virions, negatively contrasted with 1% ammonium molybdate.

BBTV isolates worldwide fall into two broad phylogenetic groups (Fig. 1), called the South Pacific (or Pacific/Indian Ocean) group (isolates from Australia, the Pacific islands the Indian sub-continent, Myanmar, Egypt and Sub-Saharan Africa) and the Asian (or South-East Asian) group (China, Philippines, Japan, Vietnam, Indonesia, Laos, Thailand and Taiwan). Sequence differences between the two groups are shared across all genome components. Within group sequence diversity is much greater for the Asian group suggesting a longer evolutionary period and possible evolutionary origin for the virus.

The coat protein gene of BBTV is highly conserved, with a maximum difference of 3% at the amino acid level between isolates. No serological differences have been detected between any isolates using polyclonal or monoclonal antibodies.

Recombination and reassortment has been detected between the two groups, supporting the temporal co-existence of the groups at one time. The most recent common ancestor of these BBTV sequences has been dated as occurring 1086 years ago (95% HPD 812–1399 years). The presence of the virus in many countries from the South Pacific group can be traced to introductions within the last century.

Virion Structure

The viral nature of bunchy top disease was established by CJP Magee in Australia in the 1920s. However, it was not until 1990 that the virus particles were first isolated, in part due to lack of a suitable herbaceous experimental host, its low titer in infected plants and its restriction to the phloem in the fibrous vascular tissue of *Musa*. Typical of the family *Nanoviridae*, BBTV has icosahedral particles, 18–20 nm in diameter with $T = 1$ symmetry (Fig. 2), a buoyant density of 1.29–1.30 g/cm³ in cesium sulfate, and a sedimentation coefficient of 46S.

Genome Organization and Functions of Gene Products

BBTV has a multi-component genome comprising six transcriptionally active components (Fig. 3, Table 1), each ca. 1 kb in size. DNA-R encodes two proteins, one the master replication initiation protein (Rep), which can initiate and terminate replication of DNA-R and the other genome components, and a second internal ORF of unknown function. All other components are monocistronic. DNA-S encodes the coat protein, demonstrated by N-terminal sequencing and the production of specific antibodies against the cloned and expressed gene. It also contributes to RNA silencing. The DNA-C gene product contains an LXCXE motif and binds to a retinoblastoma protein, indicating that it is a cell cycle link protein which stimulates viral DNA replication. It has also been linked to suppression of RNA silencing. DNA-M has been shown to be both a movement protein, and the major pathogenicity determinant and suppressor of RNA silencing. DNA-N encodes the nuclear shuttle protein, while the function of the protein encoded by DNA-U3 is unknown. The untranslated regions of all six components share two areas of extensive homology, both concerned with the rolling circle method by which BBTV replicates. A stem-loop common region (CR-SL) of 69 nt includes a nonanucleotide sequence (TATTATTAC) which is shared between plant-infecting circular ssDNA nanovirids and geminivirids, and which is the site of the origin of viral replication. It also contains three short repeated sequences (iterons F1, F2 and R1) which are the presumed binding site for the Rep. The major common region (CR-M) varies between 66 and 92 nt in length amongst the various components. Virions contain a heterogeneous population of DNA primers, around 80 nt in length, which bind to the CR-M and prime complementary strand synthesis. The relative concentrations of the genome components can vary enormously with DNA-S generally being the least abundant in plants, and DNA-N the highest, at 60 to >1660 times the copy number of DNA-S.

The intergenic regions of all six integral components of BBTV have been shown to have promoter activity. The highest activity in banana embryonic cells was shown by promoters from DNA-C and DNA-M, components thought to be intrinsic to the infection process. Studies on the DNA-N promoter demonstrated that expression in banana embryonic cells is limited to phloem tissue,

Fig. 3 Diagram of the integral genome components of BBTV, showing transcribed ORFs (black arrows) and other main genome features. From Fauquet, C.M., Mayo, M.A., Maniloff, J., Desselberger, U., Ball, L.A., 2005. *Virus Taxonomy*. Eighth Report of the International Committee on Taxonomy of Viruses. San Diego, CA: Elsevier Academic Press.

Table 1 Size and function of the six integral components of BBTV

Genome component	Size (nt)	Size of encoded protein(s) (kDa)	Function
DNA-R	1111	(i) 33.6 (ii) 5.2	(i) Replication initiation protein (ii) Unknown
DNA-S	1075	20.1	Capsid protein
DNA-M	1043	13.7	Movement protein
DNA-C	1018	19.0	Cell-cycle link
DNA-N	1089	17.4	Nuclear shuttle protein
DNA-U3	1060	10.4	unknown

consistent with the circulative mode of transmission by the aphid vector and observations that histological effects were confined to the phloem and phloem parenchyma cells. Circulative transmission by aphid vectors usually involves specific feeding on the phloem tissue for virus acquisition. The CR-M and CR-SL are not essential for promoter activity. All essential elements of the promoter are located 3' of the stem-loop and within 239 bp of the translation start codon and within this region are an ASF-1 motif (TGACG), a hexamer motif (ACGTCA), *rbcS*-I-box (GATAAG), G-boxcore and the TATA box, all associated with promoter activity in other genomes.

Some isolates of BBTV, especially those from the South-East Asian group (see Taxonomy and Phylogenetic Relationships), contain additional Rep proteins called alphasatellites, similar in size to DNA-R, but capable of self-replication only. These molecules have a CR-SL, though the nonanucleotide sequence TAGTATTAC forming part of the loop is not conserved with the six integral DNA components. Unlike DNA-R, the alphasatellites lack the internal ORF, their TATA boxes are 5' of the stem loop and they generally lack the CR-M. Interestingly, the amino acid sequences of BBTV alphasatellites are more closely related phylogenetically to the alphasatellites associated with viruses in the related genus *Nanovirus* than they are to DNA-R of BBTV. The biological function of the alphasatellites is uncertain.

Host Range and Transmission

The symptoms of bunchy top disease in banana are characteristic, especially in the Cavendish subgroup of cultivars, and easily distinguished from all other virus diseases of banana. Plants can become infected at any stage of growth, and the initial appearance of symptoms can depend on the manner of infection. Plants that are aphid-inoculated usually develop first symptoms in the second or later leaves to emerge after inoculation, and there display a few dark green streaks and dots on the lower part of the lamina and on the petiole. These symptoms become more general on subsequent leaves. These streaks form hooks as they enter the midrib and are best viewed from the underside of the leaf, with transmitted light (Fig. 4). However, these dark streaks can be rare or absent in some cultivars. Successive leaves become shorter and narrower, and have a brittle lamina with upturned, chlorotic, ragged margins. Leaves fail to emerge fully, giving the plant a bunched appearance (Fig. 5). Plants derived from infected planting material (suckers, bits) develop severe symptoms from the first leaf to emerge.

Fig. 4 Dark green dot-dash, hooking and vein clearing fleck symptoms on a Cavendish banana leaf.

Infected plants seldom produce a bunch, though if infected late in the current cropping cycle, a small, distorted bunch may result. With very late infections, the only symptoms to appear in the current season may be a few dark streaks on the tips of the flower bracts. No fruit is produced in subsequent years, and plants generally die within a couple of years.

From Taiwan, symptomless strains of BBTV, and mild strains that produce only limited vein clearing and dark green streaks have been reported. Interestingly, DNA-N could not be detected in the mild strain infection. Also, some field plants of the Cavendish subgroup cultivar Veimama from Fiji have been observed to initially show severe symptoms, then to recover and display few if any symptoms. This phenomenon has also been observed in the greenhouse in Cavendish cv Williams.

Confirmed hosts of BBTV are mostly confined to the family Musaceae. Known susceptible hosts include *Musa* species, cultivars in the Eumusa and Australimusa series of edible banana and *Ensete ventricosum*. Susceptible *Musa* species include *M. balbisiana*, *M. acuminata* ssp. *banksii*, *Musa acuminata* ssp. *halabanensis*, *M. acuminata* ssp. *longipetiolata*, *Musa acuminata* ssp. *malaccensis*, *M. acuminata* ssp. *zebrina*, *M. coccinea*, *M. jackeyi*, and *M. ornata*. *M. textilis*, *M. velutina*. There are some valid reports of hosts outside the Musaceae, in species in the Zingiberales, including *Alpinia purpurata*, *A. zerumbet*, *Canna indica*, *Colocasia esculenta* and *Hedychium coronarium* and from the Alismatales, *Colocasia esculenta*. However, using other virus isolates, not all tests to infect these hosts have been successful.

Although there are no confirmed reports of immunity to BBTV in *Musa* sp., there are many reports of differences in susceptibility and symptom expression between cultivars.

The banana aphid (*Pentalonia nigronervosa*) has a worldwide distribution in tropical and sub-tropical regions where banana is grown, and in 1925 was shown to be a vector of BBTV. Using morphological and molecular methods, *P. nigronervosa* f sp. *caladii* was resurrected as a distinct species, *P. caladii*. Both species are vectors of this virus. The host ranges of both aphid species show considerable overlap, though *P. nigronervosa* is found predominantly on *Musa* sp., while *P. caladii* occurs mostly on related hosts in the Zingiberales. On banana, they commonly colonize the base of the pseudostem at soil level and for several centimeters below the soil surface, beneath the outer leaf sheaths and newly emerging suckers.

Transmission by *P. nigronervosa* is of the persistent, circulative, non-propagative type, and the virus has been demonstrated to accumulate in the anterior midgut, hemolymph and principal salivary glands. Individuals from areas where BBTV is endemic and from where it is absent, both transmit the virus with equal efficiency. There is a minimum acquisition access period of 4 h, a minimum latent period of a few hours, and a minimum inoculation access period of 15 min. Aphids retain infectivity, after removal from a virus source, for at least 20 days and probably for life. Both nymphs and adults can acquire the virus, though the former a more efficient, and reported transmission rates for individual aphids are in the range 46%–67%. There is no evidence for transmission of BBTV to parthenogenetic offspring or for replication of the virus in the aphid.

BBTV is also efficiently transmitted in vegetative planting material, both conventional corms, corm pieces (bits) and suckers, and through micropropagation. All meristems from an infected corm will eventually become infected.

Virus–Host Relationships

BBTV is systemic within the banana plant, and following aphid inoculation, symptoms do not appear until at least two more new leaves have been produced (bananas produce single new leaves sequentially from a basal meristem). Histological examination suggests that BBTV is restricted to the phloem tissue, which shows hypertrophy and hyperplasia and a reduction in the

Fig. 5 Young BBTV-infected banana plants, showing stunting, and successively shorter narrow leaves with upturned, chlorotic margins. Leaves have failed to emerge fully, giving the plant a bunched appearance.

development of the fibrous schlerenchyma sheaths surrounding the vascular bundles. The cells surrounding the phloem contained abnormally large numbers of chloroplasts, resulting in the macroscopic dark green streak symptom.

It has been demonstrated through, the use of RNA probes and PCR, that BBTV replicates briefly at the site of aphid inoculation, then moves down the pseudostem to the basal meristem, subsequently infecting the newly formed leaves, the corm and the roots. The virus apparently does not replicate in leaves formed prior to infection, consistent with the lack of symptoms on these leaves and an inability to recover the virus from them via the aphid vector.

BBTV has been detected in most parts of the banana plant, including the leaf lamina and midrib, pseudostem, corm, meristems, roots, fruit stalk and fruit rind.

Diagnosis

The characteristic symptoms expressed by BBTV-infected plants allow symptomatology to be used to identify infected plants in field survey and control activities. However, BBTV is sometimes symptomless in tissue culture and the use of laboratory detection assays is desirable in the provision of clean planting material. Polyclonal and monoclonal antibodies to BBTV are used in ELISA to detect the virus in field and tissue culture plants and can detect the virus in single viruliferous aphids. Polymerase chain reaction (PCR) was shown to be about one thousand times more sensitive than ELISA or dot blots with DNA probes. Substances in banana sap inhibitory to PCR can be circumvented by simple extraction procedures or by immunocapture PCR. Nucleic acid-based loop mediated isothermal amplification (LAMP) and recombinase polymerase amplification (RPA) assays have also been described for the detection of BBTV.

Geographical Distribution

Historical Records and Possible Origins

The origin of BBTV is unclear. The first records were from Fiji in 1889, and though reports and photographs clearly indicate that it was present at least 10 years prior, soon after the establishment of an export industry based on Cavendish cultivars, evidence suggests that the disease did not originate there. Other early recorded are from Egypt (1901 – source unknown) and Australia and Sri Lanka both in 1913, and probably from planting material imported from Fiji.

Considerably more genetic diversity, and also a greater incidence of alphasatellites is found in BBTV isolates from South-East Asia. The aphid vector and the wild progenitors of modern edible bananas also originated in the South and South-East Asian-Australasian region, and the Cavendish cultivars of international trade and associated with early outbreaks of bunchy top disease, are thought to have originated in South-southern China/northern Vietnam. These factors lead to speculation that BBTV also originated and evolved in this region.

BBTV has a widespread, but scattered distribution in many of the banana-growing countries of the Asia-Pacific regions and Africa, but at present is not found in the Americas. In some countries the distribution is localized. For example, in Australia it is present only in southern Queensland and northern New South Wales, but not in the major production area of north Queensland. Banana bunchy top disease has been recorded in the following countries:

Africa: Angola, Benin, Burundi, Cameroon, Central African Republic, Congo Republic (Congo-Brazzaville), Democratic Republic of Congo (formerly Zaire), Egypt, Gabon, Malawi, Mozambique, Nigeria, Rwanda, South Africa, Zambia.

Asia: Bangladesh, Cambodia, China, Hong Kong, Indonesia, India, Iran, Japan (Ogasawara-gunto, formerly Bonin Island, Okinawa), Korea, Laos, Malaysia (Sarawak), Myanmar, Pakistan, Philippines, Sri Lanka, Taiwan, Thailand, Vietnam.

Oceania: Australia, Fiji, Guam, Kiribati (formerly Gilbert Islands), Marianas Islands (Guam, Saipan, Tinian and Rota), New Caledonia, Samoa, Tahiti, Tonga, Tuvalu (formerly Ellice Islands), USA (American Samoa, Hawaii), Wallis Island.

Epidemiology and Control of BBTV

Outbreaks of bunchy top disease can have a devastating effect on banana production, especially industries based on Cavendish cultivars. Production in Fiji fell by more than 80% from 1892 to 1895, primarily due to bunchy top disease. By 1925, around 10 years from the introduction of BBTV to Australia, the banana industry in northern New South Wales and southern Queensland had collapsed, with most plantations affected and production decreased by 90%–95%. Magee noted at the time “It would be difficult for anyone who has not visited these devastated areas to visualize the completeness of the destruction wrought in such a short time by a plant disease”.

More recently, a severe outbreak of banana bunchy top disease occurred in Pakistan. From 1991–1992, production area fell by 55% and total production by 90%, as a direct result of the disease. The disease has also recently appeared in Hawaii, New Caledonia, Benin, Nigeria, Mozambique and Malawi, all with severe impact in the affected areas.

The epidemiology of banana bunchy top disease is simplified by the occurrence of a single insect vector species and a limited host range for the virus, usually cultivated or feral edible bananas. Long distance spread is usually via infected planting material, and local spread via aphids and planting material.

Analysis of actual outbreaks of bunchy top disease in commercial banana plantations in Australia showed that the average distance of secondary spread by aphids was only 15.5–17.2 m, with nearly two-thirds of new infections less than 20 m from the nearest source of infection and 99% less than 86 m. Isolation of new plantations has a marked effect on reducing the risk of infection. New plantations situated adjacent to affected plantations had an 88% chance of recording infections in the first year. This was reduced to 27% if the plantations were separated by 50–1000 m, and to 5% if separated by more than 1000 m. The disease latent period (i.e., period from inoculation of a plant until an aphid can transmit the virus from this plant to another) is equivalent to the time taken for 3.7 new leaves to emerge from the plant. The actual time varies seasonally depending on the rate of leaf production.

Control strategies were devised by CJP Magee in the 1920s, and these measures still form the basis of the very successful control program in Australia today. The two major elements of the strategy are (1) exclusion of the disease from unaffected and lightly affected areas and (2) eradication of infected plants from both lightly and heavily-affected areas.

These measures require the participation of all growers and are unlikely to succeed if left to the goodwill of growers alone and are thus enforced by legislation in Australia. The measures include:

- (1) Registration of all banana plantations.
- (2) Establishment of quarantine zones.
- (3) Restrictions on the movement and use of planting material.
- (4) Regular inspections of all banana plantations for bunchy top.
- (5) Prompt destruction of all infected plants.
- (6) Ongoing education and extension programs for growers.

When adopted, these measures allowed the complete rehabilitation of the Australian banana industry. Sometimes total eradication of BBTV from a district has been achieved, but in most cases, incidence has been reduced to very low, manageable levels. Such successful control of bunchy top is rarely achieved in other countries, in most cases due to an inability to enforce an organized control program across whole districts.

There are no confirmed reports of immunity to BBTV in *Musa*. However, it has frequently been observed that there are differences in susceptibility between cultivars to both field and experimental infection. Edible bananas have diploid, triploid or tetraploid genomes containing, predominantly, elements of the *M. acuminata* (A), or *M. balbisiana* (B) genomes. Cultivars in the Cavendish subgroup (AAA genome), which dominates the international export trade, and many other A genome cultivars are highly susceptible and show severe disease symptoms. Interestingly, however, Gros Michel (AAA) displays resistance to the disease under both experimental inoculation and field conditions. Compared with highly sensitive cultivars such as Cavendish, the cultivar is less susceptible to aphid inoculation, contains a lower level of virions in infected plants, and symptoms are less severe and develop more slowly. These factors may contribute to a reduced rate of aphid transmission and field spread in plantations of Gros Michel, and introduction of this cultivar may explain the partial recovery of the Fijian banana industry after devastation of the Cavendish-based industry in the early 1900s. Field observations and glasshouse inoculations suggest that some B genome-containing cultivars are less susceptible to infection and/or display more limited symptoms, but this needs to be further investigated.

In glasshouse trials, the RNAi strategy for BBTV resistance based on DNA-R sequences has been shown to be effective in India and with DNA-M in Australia. In Malawi, initial field testing of transgenic bananas with RNAi-based BBTV resistance was less successful.

This is an update L.L. Domier, Barley Yellow Dwarf Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00637-3.

Glossary

Hemocoel The primary body cavity of most arthropods that contains most of the major organs and through which the hemolymph circulates.

Hemolymph A circulatory fluid in the body cavities (hemocoels) and tissues of arthropods that is analogous to blood and/or lymph of vertebrates.

Introduction

Barley yellow dwarf disease (BYD) is one of the most economically important virus diseases of cereals, and is found in almost every grain growing region in the world. Widespread BYD outbreaks in cereals were noted in the United States in 1907 and 1949. However, it was not until 1951 that a virus was proposed as the cause of the disease. The causal agents of BYD are obligately transmitted by aphids, which probably delayed the initial classification of BYD as a virus disease. Subsequently, BYD was shown to be caused by three species of Barley yellow dwarf virus (BYDV), a species of Cereal yellow dwarf virus (CYDV) and a species of Maize yellow dwarf virus (MYDV). Depending on the virulence of the virus strain, infection may contribute to winter kill in regions with harsh winters, induce plant stunting, inhibit root growth, reduce or prevent heading, or increase plant susceptibility to opportunistic pathogens and other stresses. Yield losses to wheat in the United States alone are estimated at 1%–3% annually, exceeding 30% in certain regions in epidemic years. The effects of BYD in barley and oats typically are more severe than in maize and wheat; sometimes resulting in complete crop losses. The existence of multiple strains and species of viruses that are transmitted in strain-specific manner made the viruses model systems to study interactions between viruses and aphid vectors in the circulative transmission of plant viruses. In addition, the compact genomes of the viruses have provided useful insights into the manipulation of host translation machinery by RNA viruses.

Taxonomy and Classification

The viruses that cause BYD are members of the family *Luteoviridae*, and were first grouped because of their common biological properties. These properties included persistent transmission by aphid vectors, the induction of yellowing symptoms in grasses, and serological relatedness. Different viruses are transmitted more efficiently by different species of aphids, a fact that was originally used to distinguish the viruses. Around 1960, the viruses were separated into five 'strains' (now recognized as distinct species) based on their primary aphid vectors. BYD-causing viruses transmitted most efficiently by *Sitobion* (formerly *Macrosiphum*) *avenae* were assigned the acronym MAV, for *Macrosiphum avenae* virus. Similarly, viruses transmitted most efficiently by *Rhopalosiphum maidis* and *Rhopalosiphum padi* were assigned the acronyms RMV and RPV, respectively. Viruses transmitted most efficiently by *Schizaphis graminum* were assigned the acronym SGV. Finally, vector-nonspecific viruses, that is, viruses transmitted efficiently by both *R. padi* and *S. avenae* were assigned the acronym PAV. The abbreviations now are assigned to BYDV-MAV, BYDV-PAV, BYDV-SGV, CYDV-RPV and MYDV-RMV. Subsequently, additional species were described, including a severe BYDV (BYDV-PAS) and a severe CYDV (CYDV-RPS). Prevalent BYD-causing viruses from China also have been named, including a *Luteovirus*, BYDV-GAV, which is a strain of BYDV-MAV transmitted by *S. graminum* and *S. avenae*, and a *Polerovirus* named wheat yellow dwarf virus-GPV (WYDV-GPV) transmitted by *R. padi* and *S. graminum*. Recently, two new BYDV species, BYDV-kerII and BYDV-kerIII, were identified in native grasses on the Keruelen islands in the Antarctic that are thought to have been introduced along with *R. padi* during the second half of the 20th century.

Based on genome organization and predicted amino acid sequence similarities, BYDV-MAV, BYDV-kerII, BYDV-kerIII, BYDV-PAS, and BYDV-PAV have been assigned to the genus *Luteovirus*, and CYDV-RPS, CYDV-RPV, MYDV-RMV and WYDV-GPV to the genus *Polerovirus*. The RNA-dependent RNA polymerases (RdRps) encoded by open reading frames (ORFs) 1 and 2 of luteoviruses are phylogenetically related to those of members of the family *Tombusviridae* (Fig. 1). In contrast, the predicted amino acid sequences of the RdRps encoded by ORFs 1 and 2 of poleroviruses are phylogenetically related to those of viruses in the family *Solemoviridae*. The two polymerase types are distantly related in evolutionary terms. For this reason, BYDV-SGV has not been definitively assigned to a genus because its genome has not been completely sequenced. The divergent origin of the RdRp sequences suggest that the genomic RNAs of luteoviruses and poleroviruses were formed by recombination between RNAs expressing a common set of structural and movement proteins and RNAs expressing two different sets of replication proteins. Because of these differences, it has been suggested that luteoviruses should be placed in the family *Tombusviridae* and poleroviruses in the family *Solemoviridae*.

Fig. 1 Phylogenetic relationships of the predicted amino acid sequences of RNA-dependent RNA polymerases (RdRps) encoded by ORF2s of barley yellow dwarf (BYD)-causing viruses and selected members of the families *Solemoviridae* and *Tombusviridae*. The RdRps of BYD-causing luteoviruses are more similar to those of members of the family *Tombusviridae* than to those of BYD-causing poleroviruses. Similarly, the RdRp amino acid sequences of BYD-causing poleroviruses and Potato leaf roll virus (type member of the genus *Pterovirus*) are more similar to those of members of the family *Solemoviridae* than to those of BYD-causing luteoviruses. The resulting consensus tree from 500 bootstrap replications is shown. The numbers next to each node indicate the percentage of bootstrap replicates in which that node was recovered.

Virion Properties and Composition

All members of the family *Luteoviridae* have non-enveloped icosahedral particles with diameters of 25–28 nm (Fig. 2). Capsids are composed of major (22 kDa) and minor (65–72 kDa) coat proteins (CPs). The minor CP is formed by a carboxy-terminal extension to the major CP called the readthrough domain (RTD). According to X-ray diffraction and molecular mass analysis, virions consist of 180 protein subunits, arranged in $T = 3$ icosahedra. Virus particles do not contain lipids or carbohydrates, and have sedimentation coefficients $s_{20,w}$ (in Svedberg units) that range from 115 to 118 S. Buoyant densities in CsCl are approximately 1.4 g cm^{-3} . Virions are moderately stable, insensitive to freezing, and are insensitive to treatment with chloroform or nonionic detergents but are disrupted by prolonged treatment with high concentrations of salts. Table 1.

Genome Organization and Expression

Genomic RNAs of BYDV-causing viruses for which complete nucleotide sequences are available contain six to seven ORFs (Fig. 3). ORFs 1, 2, 3, 3a, 4 and 5 are shared among all the viruses. BYDVs lack ORF0. Genomic sequences of some BYDVs contain a small ORF, ORF6, downstream of ORF5. In poleroviruses, ORFs 0 and 1 and ORFs 1 and 2 overlap by more than 600 nt. In BYDVs, ORF1 overlaps ORF2 by less than 50 nt. In BYDV-causing virus genome sequences, ORF4 is contained within ORF3. An amber (UAG) termination codon separates ORFs 3 and 5.

The genomes of BYD-causing viruses have relatively short 5' ends and intergenic non-coding regions. ORFs 2 and 3 are separated by about 200 nt. The lengths of non-coding sequences downstream of ORF5 are very different between BYDVs and BYD-causing viruses. BYDV-PAV contains over 860 nt downstream of ORF5 compared to just 170 nt for CYDV-RPV.

The expression of BYDV-PAV RNA has been studied in detail and has revealed a complex set of RNA–RNA and RNA–protein interactions that are employed to express and replicate the virus genome. Less experimental data are available for BYDV-causing poleroviruses. However, expression and replication strategies and gene functions can be inferred from those of closely related poleroviruses, particularly Beet western yellows virus (BWYV) and Potato leaf roll virus (PLRV). ORFs 0, 1, and 2 are expressed directly from genomic RNAs. Downstream ORFs are expressed from subgenomic RNAs (sgRNAs) that are transcribed from internal initiation sites by virus-encoded RdRps from negative-strand RNAs and are 3'-coterminal with the genomic RNA. Since the initiation codon for ORF0 of poleroviruses is upstream of that of ORF1, translation of ORF1 is initiated by 'leaky scanning' in which ribosomes bypass the AUG initiation codon of ORF0 and continue to scan the genomic RNA until they reach the initiation codon of ORF1. The protein products of ORF2 are expressed only as a translational fusion with the product of ORF1. At a low frequency during the expression of ORF1, translation continues into ORF2 through a -1 frameshift that produces a large protein containing sequences encoded by both ORFs 1 and 2 in a single polypeptide. The frameshift is mediated by a

Fig. 2 Scanning electron micrograph of barley yellow dwarf virus-PAV particles, magnified $200,000\times$. Virions are c. 25 nm in diameter, hexagonal in appearance, and have no envelope and encapsidate a c. 5.6 kb molecule of single-stranded, positive-sense RNA. CYDV-RPV virions also encapsidate a 322-nucleotide satellite RNA that accumulates to high levels in the presence of the helper virus.

“slippery heptanucleotide sequence” (in the form X XXY YYZ) and a downstream RNA secondary structure termed a pseudoknot that causes ribosomes to pause and then shift back one nucleotide before continuing translation in the new reading frame. In BYDV-PAV, frameshifting between ORFs 1 and 2 also is dependent upon the interaction of RNA sequences close to the site of frameshifting and a long-distance frameshift element (LDfE) located 4000 nt downstream in the 3′ non-coding region of genomic RNAs. Mutations that disrupt the interactions between these two distal regions suppress frameshifting and abolish RNA replication.

ORFs 3, 3a, and 4 are expressed from the 5′ terminus of sgRNA1 by a leaky scanning mechanism much like that used to express ORF1 of BYDV-causing poleroviruses. The 5′ terminus of sgRNA1 is located about 200 nt upstream of ORF3, and the 3′ terminus is co-terminal with the genome. ORF3a is initiated as a non-AUG codon. The product of ORF5 is expressed only as a translational fusion with the products of ORF3 by readthrough of the UAG termination codon at the end of ORF3. This produces a protein with the product of ORF3 at its amino terminus and the product of ORF5 at its carboxyl terminus. Readthrough is regulated by local and long-distance RNA-RNA interactions. BYDVs produce two additional sgRNAs. sgRNA2 contains ORF6, but sgRNA3 does not contain a predicted ORF.

While genomic RNAs of BYDV-causing poleroviruses contain 5′ VPgs that interact with translation initiation factors, BYDV-PAV RNA contains only a 5′ phosphate. Unmodified 5′ termini usually are recognized poorly for translation initiation. To circumvent this problem, a short sequence located in the noncoding region just downstream of ORF5 in the BYDV-PAV genome, called the BYDV translation enhancer (BTE), promotes efficient cap-independent translation initiation by directly interacting with eukaryotic translation initiation factor 4E and sequences near the 5′ termini of the genomic and sgRNA1.

Fig. 3 Genome organizations of Barley yellow dwarf virus-PAV (BYDV-PAV) and Cereal yellow dwarf virus-RPV (CYDV-RPV). Individual open reading frames (ORFs) are shown as staggered open boxes. The predicted sizes of the protein products are indicated. The genome-linked protein (VPg) attached to the 5' terminus of CYDV RNA is indicated by a solid circle. Based on homology to other viruses ORF0 encodes a silencing suppressor and ORFs 1 and 2 encode replication-related proteins. ORFs 3 and 5 encode the major coat protein and readthrough domain, respectively. ORF3a, which is initiated at a non-AUG codon, encodes a protein required for long-distance movement. ORF4 encodes a protein required for virus cell-to-cell movement. The BYDV translation enhancer (BTE) facilitates translation initiation of BYDV-PAV genomic RNA and subgenomic RNA1 (sgRNA1). In both BYDV-PAV and CYDV-RPV, ORF2 is expressed as a translational fusion with the product of ORF1 via a -1 frameshift. In BYDV-PAV, frameshifting requires interaction between the 5' frameshift signals and the long-distance frameshift element (LDfE). Dashed lines indicate long-distance RNA–RNA interactions. GNRA tetraloops at the 3' terminus of BYDV-PAV genomic RNA are required for negative-strand RNA synthesis and virus replication.

Functions of BYDV and CYDV proteins have been ascribed based on homology to virus proteins with known functions and mutational characterization of protein coding regions. Similar to BWYV and PLRV, the proteins encoded by ORF0s of BYD-causing poleroviruses are inhibitors of local and systemic post-transcriptional gene silencing (PTGS). PTGS is an innate and highly adaptive antiviral defense found in all eukaryotes that is activated by double-stranded RNAs (dsRNAs), which are produced during virus replication. Furthermore, researchers noted a correlation between symptom severity and the strength of PTGS suppression of ORF0-encoded proteins of CYDV-RPV and CYDV-RPS. The genomes of BYDVs lack an ORF0, but the product of ORF4 functions as an inhibitor of systemic PTGS in those viruses. The ORF1-encoded proteins of BYD-causing poleroviruses contain the VPg and a chymotrypsin-like serine protease that is responsible for the proteolytic processing of ORF1-encoded polyproteins. The protease cleaves the ORF1 protein in trans to liberate the VPg, which is covalently attached to genomic RNAs. ORF2s, which are expressed as translational fusions with the product of ORF1, have coding capacities of 59–72 kDa and predicted amino acid sequences that are very similar to known RdRps and likely represent the catalytic portion of the viral replicase.

Fig. 4 Circulative transmission of BYD-causing viruses by vector aphids. While feeding from sieve tubes of an infected plant, an aphid (shown in cross section) acquires virions, which travel up the stylet, through the food canal, and into the foregut. Virions are actively transported across cells of the hindgut into the hemocoel and then passively diffuse through the hemolymph to the accessory salivary gland where they are again actively transported into the lumen of the gland. Once in the salivary gland lumen, the virions are expelled with the saliva into the vascular tissue of host plants. Viruses that are not transmitted by a particular species of aphid often accumulate in the hemocoel, but do not traverse the membranes of the accessory salivary gland.

ORF3a expresses highly conserved 4.8–5.3 kDa proteins that are essential for long-distance movement. ORF3 encodes the major 22 kDa CP. ORF5 has a coding capacity of 43–50 kDa, which is expressed only as a translational fusion with the product of ORF3 when translation reads through the termination codon at the end of ORF3 and continues through to the end of ORF5. The ORF5 portion of this readthrough protein has been implicated in aphid transmission and virus stability. Recombinant viruses that do not express ORF5 produce virions assembled from the major CP alone, which are not transmitted by aphid vectors and are less efficient in systemic infection of host plants than wild-type viruses. The amino-terminal portions of ORF5 proteins are highly conserved among BYD-causing viruses, while the carboxyl termini are much more variable. Proteins encoded by ORF4 are thought to facilitate intra- and intercellular virus movement because viruses with mutations in ORF4 are able to replicate in isolated plant protoplasts, but are deficient or delayed in systemic movement in whole plants.

Some BYDV genomic sequences contain an ORF6 downstream of ORF5. The predicted sizes of the proteins expressed by ORF6 range from 4 to 7 kDa. The predicted amino acid sequences of the proteins encoded by ORF6 are poorly conserved among BYDV-PAV isolates. Repeated attempts to detect protein products of ORF6 have been unsuccessful. In addition, BYDV-PAV genomes into which mutations have been introduced that disrupt ORF6 translation are still able to replicate in protoplasts. Based on these observations, it has been concluded that ORF6 is not translated *in vivo*. However, sgRNA2, which contains ORF6, has been shown to inhibit translation of capped and polyadenylated mRNAs, and hence, may function as a negative riboregulator of host translation.

Host Range and Transmission

BYD-causing viruses infect over 150 species of annual and perennial grasses in five of the six subfamilies of the Poaceae. The feeding habits of vector aphids have a major impact on the host ranges of virus species. Hence, the number of species naturally infected by the viruses is much lower than their experimental host ranges. As techniques for infecting plants with recombinant viruses have improved, the experimental host ranges of the viruses have been expanded to include plants on which aphid vectors would not normally feed. For example, BYDV-PAV and CYDV-RPV have been shown to infect *Nicotiana* species when inoculated using *Agrobacterium tumefaciens* harboring binary plasmids containing infectious copies of the viruses, which had not been described previously as experimental hosts for the viruses.

Viruses that cause BYD are transmitted in a circulative strain-specific manner by at least 25 aphid species. Circulative transmission of the viruses is initiated when the piercing-sucking mouthparts of aphids acquire viruses from sieve tubes of infected plants during feeding. Aphids that do not probe into and feed from the vascular tissues of infected plants do not transmit the

viruses. The virions travel up the stylet, through the food canal, and into the foregut (Fig. 4). After 12–16 h, virions then are actively transported across the cells of the hindgut into the hemocoel in a process that involves receptor-mediated endocytosis of the viruses and the formation of tubular vesicles that transport viruses through epithelial cells and into the hemocoel. Virions then passively diffuse through the hemolymph to the accessory salivary gland where virions must pass through the membranes of accessory salivary gland cells in a similar type of receptor-mediated transport process to reach the lumen of the gland. The accessory salivary gland produces a watery saliva, containing few or no enzymes, that is thought to prevent phloem proteins from clogging the food canal. Once in the salivary gland lumen, virions are expelled with the watery saliva into vascular tissues of host plants. Typically, hindgut membranes are much less selective than those of the accessory salivary glands. Consequently, viruses that are not transmitted by a particular species of aphid often are transported across gut membranes and accumulate in the hemocoel, but do not traverse the membranes of the accessory salivary gland. The specificity of aphid transmission and gut tropism has been linked to the RTD of the minor capsid protein. Even though large amounts of virions can accumulate in the hemocoel, there is no evidence for virus replication in their aphid vectors. Aphids may retain the ability to transmit virus for several weeks.

Genetic and biochemical studies have been conducted to identify aphid determinants of strain-specific transmission of BYDV-MAV and BYDV-PAV. Protein–protein and protein–virus interaction experiments were used to isolate two proteins from heads of vector aphids that bind BYDV-MAV that were not detected in non-vector aphids. These two proteins are good candidates for the cell-surface receptors that are thought to be involved in strain-specific transport of viruses into accessory salivary gland lumens. In addition, endosymbiotic bacteria that reproduce in specialized cells called mycetocytes in abdomens of aphids express chaperonin-like proteins that bind BYDV particles and the amino-terminal region of recombinant BYDV-PAV RTD proteins. However, the role of these proteins in aphid transmission is unclear since they are found in both vector and non-vector aphid species. Interactions of virus particles with these proteins seem to be essential for persistence of the viruses in aphids. The proteins may protect virus particles from degradation by aphid immune systems.

Replication

Like other viruses of the family *Luteoviridae*, BYD-causing viruses infect and replicate in sieve elements and companion cells of the phloem and occasionally are found in phloem parenchyma cells. The viruses induce characteristic ultrastructural changes in infected cells. BYDV-MAV, -PAV, and -SGV induce single-membrane-bound vesicles in the cytoplasm near plasmodesmata early in infection. Subsequently, filaments are observed in nuclei, and virus particles are first observed in the cytoplasm. In contrast, CYDV-RPV and MYDV-RMV induce double-membrane-bound vesicles in the cytoplasm that are continuous with the endoplasmic reticulum. Later, filaments and tubules form in the cytoplasm, and CYDV-RPV and MYDV-RMV particles are first observed in nuclei.

The subcellular location of viral RNA replication has not been determined unequivocally. However, early in infection, negative-strand RNAs of BYDV-PAV are first detected in nuclei and later in the cytoplasm, which suggests that at least a portion of the BYDV-PAV replication occurs in the nucleus. A nuclear location for replication is supported by the observation that the movement protein encoded by ORF4, which also binds single-stranded RNA, localizes to the nuclear envelope and is associated with virus RNA in nuclei of infected cells. Synthesis of negative-strand RNA, which requires tetraloop structures at the 3' end of BYDV-PAV genomic RNAs, is detected in infected cells before the formation of virus particles. Because tetraloops have been implicated in RNA–protein interactions, these structures could be binding and/or recognition sites for BYDV replication proteins. BYDV-PAV sgRNAs are synthesized by internal initiation of RNA synthesis on negative-strand RNAs from three dissimilar subgenomic promoters. Late in infection, the BTE near the 5' terminus of BYDV-PAV sgRNA2 inhibits translation from genomic RNA, which may promote a switch from translation to replication and packaging of genomic RNAs. In addition to genomic RNAs, CYDV-RPV replicates a satellite RNA by a rolling-circle mechanism that generates multimeric satellite RNAs that self-cleave to unit length.

Virus–Host Relationships

Visible symptoms induced by the viruses vary greatly depending on the genotype and developmental stage of the host and strain of the virus. The most common symptoms are stunting and chlorosis. While some infected plants display no obvious symptoms, most BYD-causing viruses induce characteristic symptoms that include stunting, leaves that become thickened, curled or serrated, and yellow, orange or red leaf discoloration, particularly of older leaves of infected plants. These symptoms result from phloem necrosis that spreads from inoculated sieve elements and causes symptoms by inhibiting translocation, slowing plant growth, and inducing the loss of chlorophyll. Symptoms may persist, may vary seasonally, or may disappear soon after infection. Temperature and light intensity often affect symptom severity and development. In addition, symptoms can vary greatly with different virus isolates or strains and with different host cultivars. Yield losses caused by BYD are difficult to estimate because the viruses are so pervasive, and symptoms often are overlooked or attributed to other agents. In Australia alone, losses in barley production have been valued at over 100 million US dollars annually. Plants infected with viruses causing BYD at early developmental stages suffer the most significant yield losses, which often are linearly correlated with the incidence of virus infection.

Epidemiology

BYD infections have been reported from temperate, subtropical, and tropical regions of the world. Even though the incidence of infections of individual viruses varies from year to year and can differ among annual and perennial hosts, BYDV-PAV usually is the most prevalent of the viruses causing BYD in small grains worldwide followed by CYDV-RPV or BYDV-MAV. The remaining BYD-causing viruses are typically much less prevalent. The viruses must be reintroduced into annual crops each year by their aphid vectors. Alate, that is, winged aphids may transmit viruses from local cultivated, volunteer, or weed hosts. Alternatively, alate aphids may be transported into crops from distant locations by wind currents. These vectors may bring the virus with them, or they may first have to acquire virus from locally infected hosts. In temperate regions of Europe and North America moderate and long-distance migration of viruliferous aphids is important to development of BYD epidemics. In Australasia, and other regions with Mediterranean climates, alate aphids usually transmit viruses from relatively close infected plants. Secondary spread of the viruses is often primarily by apterous, that is, wingless aphids. The relative importance of primary introduction of viruses by alate aphids and of secondary spread of viruses by apterous aphids in disease severity varies with the virus, aphid species, crop, and environmental conditions.

Studies have shown both vector and non-vector aphids species preferred to feed on noninfected plants after having acquired BYDV virus particles, while nonviruliferous aphids preferred to feed on BYDV-infected plants. This modification of aphid behavior associated with virus acquisition could enhance the spread of virus within plant populations.

In addition to crop plants, BYD-causing viruses native and invasive annual and perennial grasses. In some cases, prevalence of BYDV in native habitats was inversely correlated with distance from cultivated cereals. Grazing of herbivores on natural grass lands was also associated with increased incidence of BYDV infections. As observed on Keruelen islands in the Antarctic, the introduction of vector aphid species into new environments can increase incidence of virus infections that negatively impacts native plant communities.

Diagnosis

Accurate diagnosis of infections has been important in understanding the transmission and epidemiology of the viruses and developing control strategies for BYD. Because BYD symptoms resemble those caused by other biotic and abiotic factors, visual diagnosis is unreliable and other methods have been developed. Initially, infectivity, or biological, assays were used to diagnose infections. In bioassays, aphids are allowed to feed on infected plants and then are transferred to indicator plants. These techniques have also been used to determine vector specificities of viruses causing BYD and to identify viruliferous vector aphids in epidemiological studies. These techniques are very sensitive but can require several weeks for symptoms to develop on indicator plants. The viruses causing BYD are strongly immunogenic, which has facilitated development of genus- and even strain-specific antibodies that have been used extensively in BYD diagnosis. Because the viruses causing BYD are present in infected tissues at very low levels, mice have been used to produce monoclonal antibodies against the viruses. Mice typically require much less viral antigen per immunization than rabbits, and hybridoma cell lines that produce monoclonal antibodies can be stored for extended periods and used for many years, which further reduces the amount of antigen needed to produce diagnostic antibodies. Techniques have also been developed to detect viral RNAs from infected plant tissues by reverse transcription polymerase chain reaction, which can be more sensitive and discriminatory than serological diagnostic techniques. Even so, serological tests are the most commonly used techniques for the detection of infections because of their simplicity, speed, and relatively low cost.

Control

Planting of insecticide-treated seeds that protect emerging seedlings from aphid infestation has been shown to reduce losses caused by BYD in Africa, Australasia and North America. Foliar applications of insecticides on older plants typically have been less effective. Alternatively, planting of tolerant or resistant cereals has proved to be a much more cost-effective and sustainable management strategy for BYD. Breeding programs have successfully integrated genes conferring high levels of tolerance into barley and oat and to a lesser extent in wheat. Even though a limited number of single genes for BYD resistance/tolerance have been identified in cultivated barley and rice, in most instances, tolerance to BYD is conditioned by multiple genes in a quantitative fashion, which has made moving BYD tolerance into new plant lines challenging. Particularly in barley, molecular markers have begun to facilitate the process of breeding for BYD tolerance. Because of a lack of effective single-gene resistance in cultivated wheat, some researchers have moved BYD resistance genes from wheat grasses (*Thinopyrum intermedium* and *Thinopyrum ponticum*) into wheat, which have provided high levels of resistance. The lack of naturally occurring resistance in cereals to BYD has made transgene-mediated resistance very attractive. Transgenic barley and oat plants have been produced that express either intact or inverted-repeat regions of the BYDV-PAV genome that conferred high levels of resistance to BYDV-PAV and closely related viruses. However, the transgenic plant lines have not been released for use by growers possibly because of the expenses of obtaining regulatory approval and/or poor acceptance of genetically modified cereal crops by grower and consumer groups.

In many small grain growing regions, viruliferous aphids arrive at similar times each spring and fall even though sizes of the aphid populations can vary significantly from year to year. In these areas, it is sometimes possible to plant crops so that young,

highly susceptible plants are not in the field when the seasonal aphid migrations occur. However, crops planted later typically do not yield as well as those planted early in the growing season. Consequently, growers must weigh the probability of obtaining higher yields against possible yield losses caused by BYD. In some instances, biological control agents such as predatory insects and parasites have reduced aphid populations significantly.

Glossary

Pathogroup A series of isolates of the same strain or pathotype (i.e., groups of isolates or strains that can be differentiated by their biological response on common bean cultivars carrying different combinations of resistance genes).

Pathotype An isolate or strain of a virus that is biologically distinct from other isolates of the same virus by virtue of differential host reactions.

Serogroup A series of isolates or strains of the same serotype.

Serotype An isolate or group of isolates that are distinguished from biologically related isolates by reaction (or lack of reaction) with key serological reagents such as defined polyclonal antisera or monoclonal antibodies.

Strain A genetic variant or subtype of a viral species.

History

Bean common mosaic virus and *Bean common mosaic necrosis virus* are species within the genus *Potyvirus*, family *Potyviridae*, and cause some of the most economically important diseases of legume crops worldwide. Yield losses due to Bean common mosaic virus (BCMV) and Bean common mosaic necrosis virus (BCMNV) may vary between 6 to 98% depending on the cultivar and time of infection. Both viruses occur essentially wherever bean and cowpea (including *Phaseolus*, *Vicia*, *Vigna*), lupin (*Lupinus*), pea (*Pisum*), peanut (*Arachis*), and soybean (*Glycine*) are grown. BCMV was first reported from the US in 1917, and the associated disease initially known as bean mosaic. It was renamed bean common mosaic in 1934 to differentiate it from bean yellow mosaic, caused by Bean yellow mosaic virus (BYMV), another potyvirus. Several pathotypes or strains of BCMV were distinguished in the 1970s by differential reactions of a number of bean cultivars, and in the early 1980s strains were further divided by serology into serotype A and serotype B. Serogroup A isolates were also biologically differentiated by temperature-insensitive induction of necrosis in bean cultivars carrying the dominant I gene. Peptide profiling of the coat protein (CP) and sequence analysis of the CP gene and 3'-untranslated region (UTR) demonstrated that the serotypes represented distinct viruses. Serotype A became known as bean common mosaic necrosis virus, while serotype B retains the name BCMV. 'Bean necrosis mosaic virus' was used for serogroup A isolates prior to acceptance of the species name bean common mosaic necrosis virus. BCMV and BCMNV also differ in particle length, CP size, and biological properties (see below). Complete genome sequences support the distinction between BCMV and BCMNV proposed using CP sequences and peptide profiles.

Taxonomy and Classification

The current criteria for differentiation of potyvirus species are <76% nt identity and <82% aa identity for the complete single ORF sequence and resulting polyprotein. The thresholds for species demarcation using nucleotide identity values for the individual coding regions range from 58% for the P1 coding region to 74%–78% for other regions. For the CP, the optimal species demarcation criterion is 76%–77% nt and 80% aa identity. Different species also often have distinct polyprotein cleavage sites. Using these criteria, *Bean common mosaic virus* and *Bean common mosaic necrosis virus* are distinct potyviral species; BCMV also now includes strains previously described by other names, including Azuki bean mosaic virus, Blackeye cowpea mosaic virus,

Dendrobium mosaic virus, Guar green sterile virus, Peanut chlorotic ring mottle virus, Peanut mild mottle virus, and Peanut stripe virus. At least 26 different strains of BCMV have been biologically authenticated as distinct on the basis of host range and host response, whereas only five biologically distinct strains of BCMNV have been recognized.

Potyviruses can be separated into at least 11 subgroups, including two 'supergroups', of which the *Bean common mosaic virus* supergroup is the largest, and the *Potato virus Y* (PVY) supergroup the second. Although 'supergroup' and 'subgroup' have no formal taxonomic meaning, it is a useful concept to describe a subset of virus species that cluster together in a phylogenetic tree (Fig. 1) and which may also have common serological properties.

BCMV and BCMNV, together with BSVA, CerMV, CABMV, CLLV, DsMV, EAPV, FVY, HarMV, IFBV, PMNV, PWV, SaLV, SaVY, SMV, TelMV, TrVY, WMV, WVMV, YBMV, ZaMMV, and ZYMV, form the BCMV supergroup (for full virus names, see Table 1). Some confusion exists in the literature over isolates described as Cowpea aphid-borne mosaic virus (CABMV); true CABMV isolates are distinct from BCMV, but some isolates initially described as CABMV were later shown to be synonymous with Blackeye cowpea mosaic virus (BlCMV), which is now recognized as a strain of BCMV.

Geographic Distribution

Many believe BCMV probably originated in Latin America, the center of diversity of *Phaseolus vulgaris*; others suggest South or East Asia. Regardless, BCMV has now spread worldwide and can be found wherever beans are grown, and in association with other bean types, as well as soybean, pea, and cowpea. Blackeye cowpea mosaic isolates are also found worldwide. Peanut stripe isolates are found in peanuts in Asia and the United States, and also infect lupin, soybean, and sesame. In many areas of the world BCMV is the most important potyvirus affecting beans, although in some areas BCMNV or BYMV may predominate. Before major efforts were made to eradicate BCMV from US germplasm collections, more than 60% of germplasm accessions were found to be infected.

BCMNV is thought to have evolved from BCMV in Central or Eastern Africa and is more important than BCMV in much of Central, Eastern, and Southern Africa, where BCMNV is common in a wide variety of wild and forage legumes as well as beans grown for human consumption. BCMNV has also been distributed throughout Africa, Europe, North and South America, largely through germplasm introductions, and has increased in importance in the United States partly as a consequence of deployment of resistance genes against BCMV (see below).

The increase in diversity and severity of bean-infecting geminiviruses in many regions has displaced BCMV and BCMNV as the most important viruses infecting beans in some areas.

Host Range and Transmission

BCMV naturally infects *P. vulgaris* (kidney bean), *P. acutifolius* (tepari bean), *P. atropurpureus*, *P. coccineus* (runner bean), *Glycine max* (soybean), *Macroptilium lathyroides* (horse gram), *Pisum sativum* (pea), *Rhynchosia minima*, *Vicia faba* (broad bean), *Vigna mungo* (black gram, urdbean), *V. radiata* (mung bean, green gram), *V. angularis* (azuki bean), and *V. unguiculata* (cowpea). Peanut stripe isolates naturally infect *Arachis hypogea* (peanut), *Lablab purpureus* (syn. *Dolichos lablab*; hyacinth bean), *Indigofera amoena*, *G. max*, *Lupinus albus* (lupin), *Pueraria phaseoloides*, *Sesamum* spp. (sesame), *Stylosanthes capitata*, and *S. craba*. Soybean isolates are adapted to soybean, and rarely infect peanuts. Dendrobium mosaic isolates infect *Dendrobium* orchids, while guar green sterile isolates infect guar (*Cyamopsis tetragonoloba*). In addition to its natural hosts, BCMV has a wide experimental host range, infecting about 100 species from 44 genera over nine families including *Amaranthaceae*, *Chenopodiaceae*, *Fabaceae*, *Solanaceae*, and *Tetragoniaceae*, although individual isolates may be much more restricted.

BCMNV naturally infects *P. vulgaris*, *P. lunatus*, *Centrosema pubescens*, *Crotalaria incana*, *Lablab purpureus*, *Senna bicapsularis*, *S. hirsuta*, *S. sophora*, and *V. vexillata*, and has been detected using a BCMNV-specific monoclonal antibody in naturally infected plants of *Albizia coriaria*, *Desmodium intortum*, *D. uncinatum*, *Rhynchosia resinosa*, *Tephrosia barbigera*, and *T. paniculata*. Experimental hosts include several other leguminous species, such as *Canavalia ensiformis*, *Crotalaria spinosa*, *Macroptilium lathyroides*, *Rhynchosia minima*, and *V. radiata*.

Both BCMV and BCMNV are transmitted by aphids in a non-persistent manner typical of viruses in the genus *Potyvirus*; the most important vector species in many countries are *Acyrtosiphon pisum*, *Aphis fabae*, and *Myzus persicae*. *Aphis craccivora* may be the most important vector in India. Minimum acquisition access and inoculation access periods are less than 1 min; no latent period is required between acquisition and inoculation. Aphid transmission is the cause of secondary transmission within the crop, but the primary means of introduction to the crop is through infected seed. Aphid transmission and infection rates tend to be higher when beans are grown under irrigation in dry regions.

Both BCMV and BCMNV are also seed-transmitted. Seed transmission varies with isolates and host species, as well as the timing of infection, but rates of up to 93% of infected seed may result from diseased plants, with erratic distribution of infected seed within individual pods. Plants infected after flowering typically do not yield infected seed, probably because the virus is not found in the embryo and cotyledons, and the virus may not be able to spread into these locations if flowering occurs prior to infection of the mother plant. Infection of the seed, and perhaps of the mother plant, can occur through infected pollen. Infectivity of the virus is retained during prolonged storage of seed. Dendrobium mosaic virus (a strain of BCMV) is transmitted by aphids and by vegetative propagation of *Dendrobium* orchids.

Fig. 1 Phylogenetic relationships of the Bean common mosaic virus subgroup. Phylogenetic relationship based on analysis of the polyprotein amino acid sequences of Bean common mosaic virus and Bean common mosaic necrosis virus with members of the BCMV subgroup, other legume-infecting potyviruses, and the genus *Potyvirus* type member, Potato virus Y (PVY). The tree was constructed by the neighbor-joining algorithm based on calculations from Clustal W pairwise amino acid sequence distances. The horizontal branch lengths are proportional to the genetic distance. The data set was subjected to 1000 bootstrap replicates. All nodes supported by >50% confidence values are shown. GenBank sequence sources are listed. Virus acronyms are as listed in Table 1; and, BYMV (Bean yellow mosaic virus), CIYVV (Clover yellow vein virus), and PSbMV (Pea seed-borne mosaic virus).

^aNames in bold italic font are species currently recognized by the ICTV.

^bNames in regular font are no longer recognized as potyvirus species, but are indented to indicate their position as strains of the species listed above. Acronyms in parentheses are no longer valid as species, but refer to strains of the virus in bold font.

^c'Bean necrosis mosaic virus' was a name used for strains of the A serotype prior to ICTV designation of these isolates as strains of BCMNV.

^dVanilla mosaic virus was recognized in the ICTV Eighth Report as a tentative species in the genus Potyvirus; recent reports suggest that it is an isolate of DsMV.

^eTricyrtis virus Y appears to meet the criteria for distinct virus species, but has not yet been recognized as such by the ICTV; the acronym is indicated only in bold font.

Properties of the Virion and Genome

Properties of particles

BCMV and BCMNV are typical of viruses in the genus *Potyvirus* in that particle preparations contain a single sedimenting (154–158S) and buoyant density component (1.31–1.32 g cm⁻³ in CsCl). Virions are non-enveloped flexuous filaments, 12–15 nm wide, and 847–886 nm (BCMV) or 810–818 nm (BCMNV) long. Virions are composed of one single-stranded RNA (ssRNA) of c. 9600 nt for BCMNV and c. 10,000 nt for BCMV (accounting for ~5% of the particle weight) encapsulated in about 1700–2000 monomer units of one CP polypeptide species with a molecular mass of c. 30 kDa for BCMNV, and c. 33 kDa for BCMV (comprising ~95% of the particle weight); a molecule of the genome-linked protein NIa-VPg is bound the 5' end of the RNA. In gel electrophoresis the CP of BCMNV migrates with apparent Mr 33 kDa, and that of BCMV of Mr 34.5–35 kDa. Virus preparations that have undergone limited proteolysis also contain lower-molecular-weight peptides of apparent Mr 29–34 kDa.

Serological relationships

BCMV and BCMNV particles are strongly immunogenic and can be easily distinguished using polyclonal antisera and monoclonal antibodies (McAbs). Polyclonal antisera show only a very distant serological relationship between strains of these two viruses. BCMV- and

BCMNV-specific antisera are available commercially for use in standard serological tests such as enzyme-linked immunosorbent assay (ELISA). Early work with BCMV and homologous antisera showed that BCMV was closely related serologically to AzMV, BICMV, PStV, and several soybean infecting-isolates from Taiwan. As noted above, these viruses are now recognized as strains of BCMV. BCMV is distantly related to BYMV, Clover yellow vein virus (CIYVV), CABMV, PVY, Passion fruit woodiness virus (PWV), SMV, Tobacco etch virus (TEV), and WVMV.

Several broad-spectrum McAbs have been identified that detect all of the strains of BCMV, including AzMV, BICMV, DeMV, and PStV, as well as the BCMV subgroup member CABMV, but not with any strains of BCMNV. Other McAbs are reported which display various degrees of specificity for these viruses (e.g., can only detect CABMV or BCMV-PStV). While these McAbs can be used to discriminate among the BCMV isolates, biological diversity among these viruses may limit the use of many of these antibodies for diagnostic purposes. Most McAbs produced to BCMNV are specific only for strains of BCMNV (i.e., have no cross-reactivity with any strains of BCMV, nor other potyviruses).

Another series of McAbs were raised against three strains of BCMV (AzMV, BICMV, and PStV). Results of ELISA, immunosorbent electron microscopy, and western-blot analyzes indicated that these McAbs are specific for a series of epitopes located entirely on the virion surface. From western-blot analyzes of untreated and trypsin- as well as endopeptidase Lys-C-treated CPs, these virus-specific epitopes appear to be located exclusively on the amino-terminus of the CP. These McAbs were found to discriminate between strains of BCMV. These and other N-terminal targeted antibodies often enable clear distinction of strains in mixed infections, but a BCMV-PStV-specific McAb that reacts well with most BCMV-PStV blotch isolates failed to detect a necrotic isolate from Taiwan and several blotch isolates from Georgia, while a BCMNV-specific McAb misdiagnosed a naturally occurring genomic recombinant between BCMV and BCMNV.

Properties of the genome and replication

The ssRNA genome, which has a VPg protein covalently linked to its 5' end, is about 10,000 nt for BCMV and 9600 nt for BCMNV. The organization of the BCMV and BCMNV genomes is similar to other potyviruses, consisting of short untranslatable sequences at the 5' and 3' ends, and a single, long open reading frame (ORF). The ORF is translated into a single polypeptide: c. 3222 aa for BCMV and c. 3071 aa for BCMNV. The polypeptide undergoes co- and post-translational proteolytic processing by three viral-encoded proteinases to form ten individual gene products. Most of the polypeptide cleavage sites differ between BCMV and BCMNV, with the exception of the HC-Pro/P3 cleavage. The ten viral proteins (Fig. 2) include, in order from the 5' end of the genome, P1 proteinase; helper component-proteinase (HC-Pro); P3; a 6 kDa protein (6K1); cylindrical inclusion (CI); a second 6 kDa protein (6K2); the nuclear inclusion "a" (Nla)-VPg protein; Nla-proteinase; nuclear inclusion "b" (Nlb); and the CP. An additional protein is translated by a frameshift within the P3 gene, resulting in production of a fusion protein, P3N-PIPO. Genomic RNA replicates via production of a full-length negative-sense RNA.

Pathogenicity, Pathology, and Resistance Genes

Isolates of BCMV and BCMNV can be differentiated into at least nine pathotypes (0, and I through VIII) based on their reactions on a series of differential bean cultivars. In susceptible bean genotypes, BCMV and BCMNV induce highly similar symptoms including mosaic, dwarfing, chlorosis and leaf curling. The intensity and severity of the symptoms depend on various parameters including the virus strain, the bean cultivar, and the age and growing conditions (temperature) of the plant when infection occurs. The difference between the two viruses relies on the phenotypes generated on resistant cultivars. BCMV normally produces only mosaic symptoms in susceptible genotypes; BCMNV isolates can induce lethal systemic necrosis and plant death in bean cultivars carrying the incompletely dominant "I" gene. In most such cultivars the systemic necrosis develops at or above 20°C; in hypersensitive genotypes the response is restricted to necrotic local lesions at normal temperatures, and systemic or "black root" symptoms only at temperatures above 30°C. Hypersensitivity results in field resistance, and is genetically dominant; no seed transmission of BCMV occurs in genotypes with the dominant "I" gene. Other resistance genes (bc-1, bc-1², bc-2, bc-2², bc-3, and bc-u) condition resistance to particular pathotypes in various combinations; the combination of the dominant I gene with the strain-specific recessive genes, bc-1², bc-2², or bc-u protects against systemic infection and seed transmission of BCMNV. In the absence of the recessive strain-specific resistance genes effective against necrosis-inducing isolates of BCMNV, the I gene alone is not sufficient to protect against systemic infection by BCMNV in many regions of Africa. The viruses carry various combinations of six pathogenicity determinants (P0, P1, P1², P2, P2², and Px), which to date have not been correlated with particular viral genes. Pathotype is not correlated with either CP or 3' UTR phylogeny, nor is there evidence for determinants controlling systemic movement in the 3'-terminal region. Evidence from

Fig. 2 Genome organization of BCMV and BCMNV. 5', 5' UTR; P1, P1 proteinase; HC-Pro, helper component-proteinase; P3, P3 protein; P3N-PIPO; 6K1, a 6 kDa protein; CI, cylindrical inclusion; 6K2, a second 6 kDa protein; Nla, nuclear inclusion "a", cleaved into VPg and Pro; VPg, genome-linked protein; Pro, proteinase; Nlb, nuclear inclusion "b"; CP, coat protein; 3', 3'-UTR. P3N-PIPO is expressed as a result of a frameshift within the P3 ORF.

natural recombinants highlights the importance of the potyviral and the P1-HC-Pro precursor protein(s) in pathogenesis and the breakage of genetic resistance (see below).

The incompletely dominant I gene was first identified in the cultivar “Corbett Refugee”, and the first recessive genes in “Robust” and “Great Northern 1” in the 1930s; strain-specificity of the recessive genes was identified in the 1950s, and the strain-unspecific gene bc-u shown in the 1970s to be necessary for expression of the strain-specific genes. Only one isolate has been identified so far that breaks resistance conferred by bc-3 (pathotype VIII); however, the gene originated in a single European breeding line, and it took many years to introgress bc-3 into genotypes adapted to the tropics. Cultivars carrying the dominant I gene may have increased susceptibility to Cowpea severe mosaic virus.

There is genetic linkage between certain seed colors and BCMV susceptibility, including red-mottled seed coat; the dominant I gene is closely linked to darker purple-mottled seed color. The lighter seed color associated with susceptibility is preferred in many cultures and commercial uses of the beans; this linkage can be partially avoided by selecting resistant types with commercially acceptable intermediate seed colors. Introgression of bc-3 can be problematic, as lines carrying the gene can be symptomless; serological or infectivity assays may be necessary to differentiate resistant and susceptible lines. Introgression of I and bc-3 has become simpler with development of molecular markers associated with each gene, allowing marker-assisted selection without virus challenge and phenotypic evaluation. The I gene is closely linked to a multigene family of TIR-NBS-LRR resistance genes conferring resistance to several related potyviruses and a comovirus.

In Latin America most black-seeded bean cultivars carry the I gene, and many additional bean lines bred at Centro Internacional de Agricultura Tropical and associated national programs also carry resistance. Many land races grown by traditional farmers, and particularly beans with light-colored seed coats, are susceptible; infection rates of up to 100%, and yield losses of 35%–98% are reported. In North America many bean varieties have effective resistance to BCMV, although many pinto, navy, and red-seeded types have only strain-specific resistance. However, recent breeding has yielded pinto and navy bean cultivars carrying both I and bc-3. BCMNV was previously rare in the US, but combined resistance to BCMV and BCMNV is now available in some cultivars of most bean types.

Many of the beans grown by small farmers in eastern and southern Africa are susceptible to both BCMV and BCMNV. The presence of necrosis-inducing strains of BCMNV, also found in wild legumes and species grown for fodder, means that the I gene cannot be deployed independent of recessive resistance genes, as infection by necrosis-inducing isolates could result in death of a significant proportion of plants in a field. In India infections of up to 100% are reported in bean, urdbean, mungbean, and cowpea, resulting in mottle, mosaic, blistering, stunting, and poor pod set. Many Asian bean types also lack resistance, due to linkage between susceptibility and desirable seed colors.

Peanut stripe strains of BCMV causing symptoms described as blotch, blotch-CP-N, blotch stripe, chlorotic line pattern, chlorotic ring mottle, mild mottle, necrosis, and stripe have also been differentiated on the basis of disease reactions on specific host genotypes. Losses of 23%–38% to peanut mild mottle have been documented in China. Peptide profiles of five symptom variants from Thailand that were not serologically distinct confirmed close relationships. No resistance was identified among over 8000 cultivated peanut genotypes in the germplasm collection at the International Crops Research Institute for the Semi-Arid Tropics. Some wild *Arachis* species have been identified as immune or highly resistant, including accession PI475998 of *A. cardenasii*, which could not be infected. Resistance genes have been identified and incorporated into resistant cultivars of *Pisum sativum*, *Lupinus angustifolius*, *Lablab purpureus*, and *Macroptilium lathyroides*.

Transgenic resistance has been demonstrated in peanut transformed with the CP gene of a peanut stripe isolate; a high level of resistance was observed in lines expressing either untranslatable or N-terminally truncated forms of the CP gene, suggesting that resistance resulted from RNA silencing (RNAi). While beans have been transformed for resistance to Bean golden mosaic virus (*Geminivirus*), and soybean for resistance to Soybean mosaic virus (*Potyvirus*), there are no reports of transgenic BCMV- or BCMNV-resistant bean lines.

Recombination and Variability

Although recombination between different isolates of BCMV had been reported for some years, no recombinants between BCMV and BCMNV were reported until recently. No recombinants were recovered from deliberate mixed infections of BCMV strain US-5 (pathogroup IV) and BCMNV strain NL-8 (pathogroup III) following many serial passages in either of two susceptible hosts. However, multiple recombinants were recovered within 28 days when the same strains were inoculated on opposite primary leaves of beans that were susceptible to one virus and resistant to the other; these recombinants fell into five different classes based on combinations of serotype (A, BCMNV; or B, BCMV) and pathogroup (IV, V, or VI). Subsequently, a naturally occurring strain of BCMNV (NL-3 K) with atypical responses on differential hosts was sequenced and shown to have a 5'-UTR and 5' region of the P1 gene almost identical to BCMV strain RU1, while the rest of the genome was almost identical to BCMNV strain NL-3 D. The P1 gene of the recombinant was larger than that of BCMNV, and similar to the BCMV P1. These results suggest that the P1 gene may play a significant role in pathogenicity and virulence, as previously suggested for BYMV.

The observed phenotypes of recombinants indicate that serotype, pathogenicity, and symptom expression are independent traits with separate determinants in the genome. The occurrence of recombination in bean genotypes with only recessive, strain-specific resistance genes suggests that this may be the primary cause of emergence of new resistance-breaking strains.

Much of the variability between isolates of either BCMV or BCMNV appears to be within the 5' portion of the genome, as has been shown both within and between other potyviruses. The P1 and P3 genes, and the N-terminal region of the CP gene are the most variable regions of the potyvirus genome, and may be involved in host–virus interactions. Differences in the 5' UTR and

N-terminus of P1 of both BCMV and BCMNV have been associated with symptom differences in common bean (*P. vulgaris*), and for BCMV in asparagus bean (*V. sesquipedalis*). Variability in the P1 gene is extensive, with as little as 61% identity at the aa level between BCMV strains, with most of the differences in the N-terminal domain. Differences in the CP gene result in clustering of BCMV isolates according to host species (bean, cowpea, peanut, asparagus bean, guar, *Dendrobium*, etc.) and to some extent by geographic origin within host clusters; peanut stripe isolates from China, Indonesia, and Thailand form separate clusters.

Diagnosis

Host range and symptomatology

Potyviruses can be detected and identified by a variety of techniques that are based on biological, cytological, biochemical, antigenic, and structural properties. With respect to BCMV and BCMNV, host range and symptomatology are not very useful because there are many viruses that infect bean, and significant differences in symptoms may be reproduced depending on the virus pathotype host genotype, and environmental conditions. Morphology of cytoplasmic inclusions has been useful in the identification of many potyviruses since inclusions can be virus-specific. However, inclusion morphology is not reliable for detection and differentiation of BCMV and BCMNV. BCMNV induces pinwheel and scroll types of cytoplasmic inclusions (subdivision I) in infected tissue. Most strains of BCMV, including BCMV-AzMV and BCMV-BICMV, also induce subdivision I type inclusions. However, PSTV and Taiwan soybean isolates induce subdivision IV cylindrical inclusions.

Serological techniques

BCMV- and BCMNV-specific polyclonal antisera and McAbs are useful for the detection and differentiation of these seed-borne viruses, and several methods have been used for detection in bean seed. When indirect ELISA and a dot immunoassay (DIA) with both McAbs and polyclonal antisera were evaluated, ELISA with McAbs proved the most sensitive method. However, BCMV antigen was found to be erratically distributed within the seed, with more than 50% of infected samples having detectable levels of BCMV antigen only in the seed coat. Tests on individual seeds proved unreliable and it is recommended that flour from a bulked sample of eight seeds be used when testing seed lots. Other assays include immunosorbent electron microscopy to detect BCMV in bean seed; or double antibody sandwich (DAS)-ELISA and bioassay on *Chenopodium quinoa* to test hydrated mature cowpea seed for presence of BCMV-BICMV. In these tests infectious virus was detected in cotyledons and sometimes in the embryonic axis of infected seed. Viral antigen was found in or on the testae, but very little infectious virus was present. Others have used direct antigen-coated-ELISA to detect BCMV-BICMV in cowpea seed.

Reverse transcription-polymerase chain reaction

The sensitivity, capacity, and potential of the PCR technique has been applied to BCMV and BCMNV. Several sets of BCMV- and BCMNV-specific RT-PCR primers have been designed and utilized to sensitively and accurately detect, differentiate, and characterize the two viral species. In one study using virus-specific CP primers, the specific geographical distribution of these viruses in Mexico was determined. In addition, the alignment of nine nucleotide sequences from cloned amplicons from the RT-PCR reactions for each viral species confirmed the identities of the viruses and was helpful in assigning them tentatively to pathogroups. Other primer sets have been developed and utilized, for example, in the successful detection and differentiation of the necrotic and blotch isolates of BCMV-PSTV, and in the differentiation of naturally occurring genomic BCMV/BCMNV recombinants. Considering the seed-borne nature of these viruses, RT-PCR has potential in quarantine programs for screening imported seed material and germplasm.

Prevention and Control

It is possible to eradicate BCMV and BCMNV from a particular production region, or at least to significantly reduce primary inoculum, by eliminating susceptible genotypes and planting only resistant varieties. There are few important non-crop reservoirs of inoculum, except in eastern and southern Africa, and infected seed are responsible for primary infections in the crop. Roguing of symptomatic plants is not recommended as a means of control, as it is highly likely that systemically infected plants without significant symptoms will remain to act as significant reservoirs for secondary infection by aphid transmission.

Exclusion of the virus is highly effective in areas where the virus is not present, but this may preclude introduction of new germplasm or cultivars without effective resistance. One or both viruses are almost universally present in seed lots of varieties that do not carry the I gene, and the majority of Latin American land race types do not possess any of the strain-specific recessive resistance genes. Most cultivars derived through extensive breeding programs carry the dominant I gene for resistance to BCMV and BCMNV. Increasingly bc-3 is being combined with I to yield cultivars with effective resistance to both BCMV and BCMNV.

Certified seed can be an effective means of control. A certified seed program in California with a limit of <0.5% BCMV has aided in the control of the disease, as resistant varieties are not yet available for all bean classes currently grown in California. Monitoring of BCMV for certification also aided in identification and containment of an outbreak of BCMNV introduced in seed of a navy bean cultivar.

Vector exclusion may aid in control, but as aphids rarely colonize common beans, migratory aphids are responsible for most transmission in many areas. As BCMV and BCMNV can be acquired and transmitted in less than 1 min access to plants, insecticide

treatment is unlikely to prevent, and may even encourage vector movement and transmission. Vector control through insecticide application may be effective in parts of Africa and Asia where aphids do colonize beans. Oil sprays are known to reduce transmission of stylet-borne viruses such as BCMV and BCMNV, but their lack of systemic action, and thus need for frequent reapplication to a growing crop, reduces the cost-effectiveness of their use.

Glossary

HTS High throughput sequencing technologies, refer to methods that are able of sequencing multiple molecules in parallel, allowing hundreds of millions of molecules to be sequenced at a time.

Hybridization probe Labeled DNA or RNA molecule (radioactively or otherwise) that will hybridize with nucleic acids with complementary sequence and will detect their presence due to the label.

PCR Polymerase chain reaction is a technique used to make multiple (millions to billions) copies of a DNA segment *in vitro* using a thermostable DNA polymerase.

Resistance Relative ability of an organism to restrict the growth and attenuate the effects of a pathogen.

RFLP Restriction fragment length polymorphism is a method to examine the genetic variation of individuals by analyzing the pattern of the fragments generated by the digestion of a specific DNA segment with endonucleases.

RNA silencing A conserved evolutionary process active in a wide variety of eukaryotic organisms that can lead to inhibition of transcription or translation of a target gene in a sequence-specific way.

RNAi A process to control gene function by harnessing the expression of a dsRNA corresponding to the sequence of a target gene. The dsRNA triggers the RNA silencing mechanism resulting in the production of small RNAs that will induce the degradation of mRNA in a sequence-specific manner, hence blocking protein production.

Introduction

The common bean (*Phaseolus vulgaris* L.) is one of the most widely cultivated legume crops in the world. Its center of origin is located in the Americas, with two major domesticated gene pools known as Andean (from the highlands of Bolivia, Ecuador and Peru) and Mesoamerican (from Mexico and Central America). Common bean is a source of carbohydrates, protein and fiber and is a major component of the human diet in Latin America, Africa and Southeast Asia. As of 2016, the world's largest producers were Myanmar, India and Brazil. In the Americas the largest producers are Brazil, the United States and Mexico, but common bean is a major crop in every country in Central and South America.

Bean golden mosaic was first reported in the mid-1960s in Brazil by A.S. Costa as a whitefly (*Bemisia tabaci* Genn.)-transmitted disease. Similar diseases were described in several Central American and Caribbean countries during the late 1960s and early 1970s, and were named either "golden mosaic" or "golden yellow mosaic". In all countries from which it was reported, the disease was associated with an increase in the population of *B. tabaci*. The similar symptoms and association with the same vector led to the assumption that the same causal agent was responsible for the disease in all countries.

Plants affected by the disease usually display striking yellow mosaic symptoms (Fig. 1), named "golden" mosaic to differentiate from the less severe common mosaic (which is usually associated with mosaic and blistering symptoms without yellowing) and yellow mosaic diseases. In reality, it may be difficult to distinguish these three diseases based solely on symptoms in the field. Additional symptoms of bean golden mosaic may include downward leaf curling, leaf distortion and stunting. A significant level of flower abortion may occur in warmer climates, contributing to yield losses.

When first reported, bean golden mosaic was considered to be of "insignificant" economic importance. However, in less than ten years it became the main disease of common bean during the dry season (Jun–Sep) in south-central Brazil, mostly due to the exponential growth in the area planted with soybean, an excellent host of *B. tabaci*. Following the harvest of soybean (Feb–May), whitefly populations migrate massively to recently planted common bean fields, and the disease causes extensive losses. As soybean became a major crop in Brazil during the 1970s, bean golden mosaic reached alarming levels and the country's bean production was greatly affected. A similar scenario occurred in Argentina. Bean golden mosaic remains a major disease in these countries and the bean industry underwent several changes as a result, including relocation to regions which are less favorable to the disease and the large-scale adoption of central pivot irrigation (which eventually led to the emergence of soil-borne diseases such as white mold). The disease also continues to be of great relevance in other Latin American countries, where the increase in whitefly populations is associated with poor management practices leading to the emergence of insecticide-resistant populations and climate change.

Ultrathin sections of leaf tissue obtained from golden mosaic-affected bean plants in Brazil revealed the presence of isometric particles (20–25 nm) restricted to vascular tissues. Probably due to its phloem-restriction, the causal agent of bean golden mosaic

Fig. 1 Bright yellow mosaic (“golden” mosaic) symptoms in common bean (*Phaseolus vulgaris*) caused by Bean golden mosaic virus (BGMV). Photograph: R. Ramos-Sobrinho.

Fig. 2 Characteristic geminate particles of BGYMV. Bar = 20 nm.

in Brazil could not be transmitted by mechanical means or by seed. Conversely, the virus associated with the disease in Puerto Rico was readily sap-transmissible. This was an early indication that the similar diseases occurring in Brazil and in Central America/Caribbean were caused by distinct, albeit related, viruses. The isolation of whitefly-transmitted viruses that induced golden mosaic symptoms in common bean was achieved in 1976 by G. Galvez and M. Castaño at CIAT, Colombia, using a bean golden yellow mosaic virus (BGYMV) isolate from El Salvador, and in 1977 by R. Goodman at the University of Illinois, USA, using a BGYMV isolate from Puerto Rico. In both cases the isolated viruses had quasi-isometric particles with a unique geminate morphology (Fig. 2). The isolate from Puerto Rico was used to characterize the viral nucleic acid. Strikingly, the viral nucleic acid was identified as a single-stranded (ss) DNA molecule, the first reported ssDNA virus in plants. In 1981, the Puerto Rican BGYMV isolate was shown to possess a two-component ssDNA genome, with each molecule (ca. 2600 nt) separately encapsidated in a geminate particle.

In 1978, BGMV from Brazil and other BGMV/BGYMV-like viruses, as well as other similar ssDNA viruses transmitted by *B. tabaci* or leafhoppers (Homoptera: Cicadellidae) were included in the newly created Geminivirus group. BGMV was classified as a “subgroup II” geminivirus (whitefly-transmitted viruses with bipartite genomes), while the leafhopper-transmitted viruses with

monopartite genomes (such as Maize streak virus) were classified as “subgroup I” geminiviruses. In 1995 the leafhopper-transmitted geminiviruses were further divided into two subgroups, and BGMV became a member of “subgroup III” geminiviruses.

Studies performed by R. L. Gilbertson and D. Maxwell at the University of Wisconsin, USA in the early 1990s using BGMV isolates from Brazil and Central American/Caribbean countries provided definitive proof that two distinct geminiviruses were associated with bean golden mosaic disease in these regions. Broad-spectrum DNA probes were obtained which were capable of detecting all isolates tested (BGMV from Brazil, Guatemala and the Dominican Republic, plus an isolate of bean dwarf virus from Colombia) under low stringency hybridization conditions. A specific DNA probe was also prepared which detected only the isolate from Brazil, and another probe detected the isolates from Guatemala and the Dominican Republic (these two isolates could not be differentiated by nucleic acid hybridization even at high stringency hybridization conditions). These assays provided strong evidence that “BGMV” isolates from Brazil and Central America/Caribbean were actually distinct viruses. In the same year, a polymerase chain reaction (PCR)-based assay was used to obtain nucleotide sequences of a hypervariable region of the viral genome (the intergenic region between the MP gene and the common region of the DNA-B component). Nucleotide sequence identities between different BGMV isolates from the Dominican Republic (95% sequence identity amongst them), Guatemala (86%), BGYMV from Puerto Rico (75%) and BGMV from Brazil (46%) further suggested the existence of significant genetic variability, particularly between the Central American/Caribbean geminiviruses and the Brazilian BGMV isolate. In 1993, the complete nucleotide sequences of the Brazilian and Puerto Rican isolates were obtained. The percent nucleotide identities between these two viruses ranged between 71% and 82%, the latter value corresponding to the coat protein gene, which is the most conserved gene among whitefly-transmitted geminiviruses. These results clearly demonstrated that BGMV from Brazil was distinct from BGYMV from Puerto Rico. The former was classified as “type I” BGMV, and the latter as “type II” BGMV. In the same year, the isolates from Guatemala and the Dominican Republic were sequenced and shown to belong to type II BGMV, together with the isolate from Puerto Rico. In 2000 the Geminivirus group became the family *Geminiviridae*, including the genus *Begomovirus* (from bean golden mosaic). Type I BGMV isolates were classified as members of the species *Bean golden mosaic virus*, while type II BGMV isolates were classified as members of the species *Bean golden yellow mosaic virus*.

The bean golden mosaic disease observed in northwestern Mexico was shown in 1992 to be caused by another distinct begomovirus originally isolated in 1981 from squash in southwestern United States, named squash leaf curl virus (SLCV). Some SLCV isolates sampled from diseased common beans in Mexico had already changed significantly and were thus classified as members of a distinct species named *Bean calico mosaic virus*. However, SLCV can still be found in northwestern Mexico causing bean calico mosaic, a severe disease that often progresses from the characteristic golden mosaic into severe foliar bleaching and plant death. In Nicaragua, bean golden mosaic was shown to be caused predominantly by BGYMV, but also by squash yellow mild mottle virus and *Calopogonium* golden mosaic virus.

In 2010, a begomovirus detected in *Macroptilium lathyroides* and named *Macroptilium yellow spot virus* (MaYSV) was shown to infect common bean in the northeastern Brazilian state of Alagoas, inducing golden mosaic symptoms indistinguishable from those caused by BGMV and BGYMV. In a large-scale survey carried out in 2011–2012, MaYSV was the predominant begomovirus detected in common bean in that state, but was not detected in the midwestern states of Goiás and Minas Gerais. More recent surveys detected MaYSV in the states of Bahia and Pernambuco, also as the predominant begomovirus in common bean. The emergence of MaYSV adds an additional layer of complexity to the scenario of bean golden mosaic in Brazil.

Taxonomy, Phylogeny, and Evolution

Currently, viruses known to cause bean golden mosaic disease are classified in three species of the genus *Begomovirus* (family *Geminiviridae*): *Bean golden mosaic virus*, *Bean golden yellow mosaic virus*, and *Macroptilium yellow spot virus*. Isolates of *Bean golden mosaic virus* (BGMV) are found in Brazil and Argentina, while isolates of *Bean golden yellow mosaic virus* (BGYMV) are found throughout Central America and the Caribbean. It is remarkable that after more than 50 years since bean golden mosaic has been described, BGMV and BGYMV remain geographically isolated. This is probably due to the presence of large geographical barriers and the lack of seed transmissibility of both viruses. Isolates of *Macroptilium yellow spot virus* (MaYSV) have only been found in the northeastern Brazilian states of Alagoas, Bahia and Pernambuco.

Phylogenetically, begomoviruses are neatly divided into Old World and New World clades. Both BGMV and BGYMV are New World (NW) begomoviruses, but within the NW clade they are distantly related. Consistent with the geography-based (rather than host-based) grouping of begomoviruses, BGMV is phylogenetically close to other begomoviruses found in Brazil, such as tomato golden mosaic virus (TGMV) and *Sida micrantha* mosaic virus (SiMMV), while BGYMV is closer to other begomoviruses found in Central America and the Caribbean such as *Macroptilium yellow mosaic virus* (MaYMV).

In 1999, samples of common bean (*P. vulgaris*), lima bean (*P. lunatus*) and the weed *Leonurus sibiricus* were collected in bean-growing areas of Brazil, and viral fragments encompassing part of the Rep gene, the common region and part of the CP gene were amplified, cloned and sequenced. The *L. sibiricus* samples were infected by a distinct virus eventually named tomato yellow spot virus, which also infects tomato and common bean but is not associated with bean golden mosaic. All sequences obtained from common bean samples were closely related to the original BGMV isolate, with <7% nucleotide sequence divergence. This was low degree of genetic variability (unlike what is found for other begomoviruses) was attributed to the lack of BGMV-resistant bean cultivars that could place selection pressure upon the viral population. A second study in 2014 confirmed the low genetic variability of BGMV populations. This study compared BGMV and MaYSV populations obtained from three hosts (common bean,

lima bean and *M. lathyroides*), and reported a much higher degree of genetic variation in MaYSV isolates compared to BGMV. This was explained by numerous recombination events in MaYSV. Recombination was much less frequent in BGMV populations. Interestingly, the genetic variability of both BGMV and MaYSV was evenly distributed among isolates infecting the different hosts, indicating that genetic variability is an intrinsic viral property which is not affected by the host. Nevertheless, BGMV and MaYSV populations showed distinct distributions of genetic variation, with the BGMV population (but not the MaYSV population) being strongly structured by both host and geography, suggesting ongoing speciation. Purifying (negative) selection is the dominant force acting on BGMV populations. Positive selection is only rarely observed, and some positively selected sites in the coat protein gene could be associated with improving whitefly transmission.

No evolutionary studies have been carried out with BGYMV populations.

Virion Structure, Genome Organization, Properties and Functions of Gene Products, Replication and Propagation

Geminivirus particles are formed from two isometric, $T = 1$ capsids fused to form a geminate particle (18×30 nm), from which the family derives its name. The geminate capsid is formed by assembly of 110 subunits of a single CP, arranged as 22 pentamers (i.e., each $T = 1$ capsid is missing one pentamer). Virion structure has not been determined in detail for BGMV or BGYMV, but it is assumed to be similar to that determined for two other begomoviruses, African cassava mosaic virus (ACMV) and Ageratum yellow vein virus (AYVV). The CP would assume three distinct conformations, facilitating the formation of the interface between the two capsids. The solution structure of the AYVV capsid confirmed the long-standing assumption that each DNA component is encapsidated in a separate geminate particle.

Complete DNA sequences of several BGMV and BGYMV isolates were determined in the late 1980s/early 1990s, and genomic organizations are essentially identical for both viruses. Thus, only the one for the Brazilian isolate of BGMV will be described in detail. The DNA-A (RefSeq accession number NC_004042, derived from M88686) and DNA-B (NC_004043, derived from M88687) are 2617 and 2580 nt long, respectively. The two components share no significant sequence identity, except for an approx. 180-nt long region known as the common region (CR), which is highly conserved (>97% identity) between the two components. The CR sequence includes direct and inverted repeats that form a stem-loop structure, with the conserved 5'-TAATATTAC-3' nona-nucleotide in the loop. In addition, two direct repeats and one inverted repeat, known as iterons (high-affinity binding sites for the Rep protein), are present upstream from the stem-loop structure.

The DNA-A has five open reading frames (ORFs): one in the viral sense (CP; previously known as AV1 or AR1) and four in the complementary sense [Rep (AC1 or AL1), TrAP (AC2 or AL2), REn (AC3 or AL3) and AC4] (Fig. 3). The complementary sense ORFs are located in different reading frames, with the 3'-end of Rep overlapping the 5'-end of TrAP, and TrAP overlapping the 5' and central regions of REn. The Rep ORF overlaps the AC4 ORF in its entirety. CP and REn overlap in opposite directions in an AT-rich region and share four nucleotides at their C-termini, which contain their translational stop codons. The DNA-B contains two non-overlapping ORFs: one in the viral sense, the nuclear shuttle protein (NSP, also BV1 or BR1), and one in the complementary sense, the cell-to-cell movement protein (MP, also BC1 or BL1). All ORFs except REn and MP have TATA boxes within 100 nt of the start codon. Polyadenylation signals are located within the AT-rich regions at or near the 3'-ends of the CP, REn and NSP ORFs. The Rep, TrAP and REn ORFs are assumed to share a single polyadenylation signal located inside the 3'-end of REn, analogous to what was shown for TGMV.

The four complementary-sense genes in the DNA-A are involved in DNA replication (Rep and REn), suppression of host defenses (TrAP and AC4) and trans-activation of the viral-sense ORFs in both the DNA-A and DNA-B (TrAP). The CP, besides its structural role, is also necessary for whitefly transmission. Together, the two DNA-B-encoded proteins coordinate viral DNA movement from the nucleus to the cytoplasm (NSP) and cell-to-cell via plasmodesmata (MP).

Fig. 3 Genome and virion structure of Bean golden mosaic virus (BGMV). The circles represent the two genomic components (DNA-A and DNA-B). The CP and NSP open reading frames are located in the viral-sense strand. Rep, TrAP, REn, AC4, and MP are located in the complementary-sense strand. CR, common region. Each genomic component is encapsidated in a separate geminate particle, as indicated below the genome structures. Thus, a virion is comprised of two geminate particles, one containing the DNA-A and the other containing the DNA-B.

Bipartite begomoviruses utilize both rolling-circle replication and recombination-dependent replication strategies. The common region contains the origin of rolling-circle replication, which is the conserved nona-nucleotide located in the stem-loop structure. The replication-associated protein (Rep) functions as a specific DNA binding protein that acts as both nuclease and ligase in the initiation and termination of the rolling-circle replication process.

In the infection process of begomoviruses, virus particles are inoculated into the plant by means of the insect vector, and the viral genome (ssDNA) disassociates spontaneously from the capsid. Viral DNA is then transported to the host cell nucleus, where the ssDNA is converted to a double-stranded dsDNA, referred to as the replicative form (RF). Indirect evidence, such as the need for local destabilization of dsDNA for initiation of rolling-circle replication in prokaryotes by strand-nicking enzymes, indicates that this is performed by host factors. The RF serves as a template for synthesis of new ssDNAs and viral mRNAs. The viral genome is replicated by the rolling-circle mechanism, similar to that used by bacteriophages phiX174 and M13, using the RF as a template. The origin of replication is the conserved nona-nucleotide (5'-TAATATTAC-3') located in the stem-loop structure in common region. Origin recognition is mediated by the high-affinity binding sites (iterons) located upstream of the stem-loop. After binding of Rep to viral DNA and stabilization of the complex formed by Rep, Ren and host factors, the Rep protein cleaves the nona-nucleotide (TAATATT//AC), initiating rolling-circle replication. Rep is the only viral protein which is essential for replication, with multiple roles. It functions as a DNA binding protein with sequence and structural requirements, and also as a nuclease and DNA ligase in the initiation and termination of the rolling-circle replication process (cleavage of the nona-nucleotide at the origin of replication; cleavage of the linear, multimeric DNA; ligation of the monomeric genome units).

As shown for other begomoviruses (Abutilon mosaic virus, African cassava mosaic virus, tomato golden mosaic virus and tomato yellow leaf curl virus), replication of BGMV and BGYMV may involve a recombination-dependent mechanism. In this mechanism, fragments of viral DNA are recovered from incomplete synthesis or from nucleolytic attack to create recombinant viruses.

Transmission, Host Range, and Epidemiology

BGMV and BGYMV have narrow host ranges. Host species are mostly restricted to the Fabaceae for both viruses. Among crop species, only *Phaseolus* spp. such as common bean (*P. vulgaris*) and lima bean (*P. lunatus*) are of significance. A.S. Costa and A.M. Almeida reported in 1979 that certain soybean (*Glycine max*) cultivars in Brazil are susceptible to BGMV. These susceptible cultivars are not considered important as virus sources for bean crops, but may probably serve as virus reservoirs between two consecutive bean plantings that coincide with the beginning and the end of the soybean growing season. The low degree of genetic variability of BGMV populations, which does not favor the emergence of new virus variants, may be one of the reasons why BGMV has never acquired economic relevance in soybean (in Brazil or in other countries).

Non-cultivated hosts of BGMV and BGYMV include *Macroptilium* spp., *Calopogonium* and wild *Phaseolus* spp. Early reports of BGMV infection in malvaceous and solanaceous hosts were probably due to mis-identification of the virus, and have not been confirmed since the use of molecular tools for virus identification became routine. It is noteworthy that fabaceous plant species used as cover crops, such as *Crotalaria* spp. and velvet bean (*Mucuna aterrina*), are non-hosts.

BGMV and BGYMV are not seedborne in any known host. BGMV from South America is not mechanically transmitted, while BGYMV from Central America and the Caribbean can be transmitted in this way with relative ease. Nevertheless, mechanical transmission is not relevant as far as virus spread in the field is concerned. The only significant form of natural transmission of both viruses in the insect vector, the whitefly *B. tabaci*.

Populations of this insect have always been recognized as genetically complex. In the past, *B. tabaci* was divided into biotypes. These are now recognized as distinct species, morphologically indistinguishable but with reproductive isolation. Up until the late-1980s, only indigenous species of *B. tabaci* such as New World 1 (NW1, previously known as biotype A) and New World 2, were present in the Americas. During the 1990s, multiple introductions of an aggressive species, *B. tabaci* Middle East-Asia Minor 1 (MEAM1, previously known as biotype B), occurred in the continent. The dissemination of *B. tabaci* MEAM1 brought dramatic changes in the incidence of begomoviruses in solanaceous crops, which are not normally colonized by *B. tabaci* NW1 but are excellent hosts for MEAM1. Although not to the same extent, MEAM1 also impacted bean golden mosaic disease. Both BGMV and BGYMV are transmitted with similar efficiencies by indigenous species and by MEAM1, but MEAM1 has a shorter life cycle and increased reproductive efficiency compared to NW1/2. Thus, MEAM1 populations reach much higher levels than NW1/2 populations, and virus transmission occurs at even higher levels. A second invasive species, *B. tabaci* Mediterranean (MED, previously known as biotype Q) has recently been introduced to South America, and is now present in southern and southeastern Brazil. The consequence of the presence of this species in the dissemination of bean golden mosaic disease is unknown, but a recent report indicated a higher efficiency of BGMV transmission by MED compared to MEAM1.

Bean golden mosaic, like other whitefly-transmitted diseases, is more severe under conditions of warm temperatures and low rainfall. In south-central Brazil, temperatures are warm during most of the year, and a pronounced dry season lasts from late June until late September. In addition, soybean crops are harvested from February until May, with massive migration of whitefly populations from soybean to other crops. As a result, June-Sep is the time of the year with the greater incidence and severity of bean golden mosaic in this region.

Virus-Host Relationships

BGMV was the object of pioneer studies on the cytopathology of geminiviruses. The 1978 work by K.S. Kim at the University of Arkansas and T. Shock and R. Goodman at the University of Illinois showed that these viruses induce major changes in the nuclear structure of infected cells, which resemble the cytopathology of animal cells infected with parvoviruses. The observed changes included the hypertrophy of the nucleolus, which eventually occupies most of the nuclear volume; the segregation of nucleolar components into granular and fibrillar regions composed of ribonucleoprotein; the presence of fibrillar rings in multiple numbers and sizes, which have been shown to contain DNA; and the appearance of viral particles either as loosely compacted aggregates or in hexagonally close-packed arrays. Virus particle aggregates were observed only in the nuclei of infected phloem cells.

Diagnosis

The correct identification of the virus infecting a plant is crucial for the selection of effective management and control procedures of the disease in the field. Bean golden mosaic disease, which is characterized by yellow and golden mosaic, leaf distortion, flower abortion, pod deformities, and stunting of plants is caused mainly by BGYMV in North and Central America and the Caribbean and by BGMV in South America. However, similar symptoms may also be induced in beans by about other 20 begomoviruses, for example, MaYSV in northeastern Brazil, tomato yellow vein streak virus in northwestern Argentina, Calopogonium golden mosaic virus in Costa Rica and Nicaragua, and also viruses from other genera and families such as alfalfa mosaic virus (fam. *Bromoviridae*, gen. *Alfamovirus*), bean yellow mosaic virus (*Potyviridae*, *Potyvirus*) and cowpea chlorotic mottle virus (*Betaflexiviridae*, *Carlavirus*) which may be present in different areas and countries. Therefore, it is not possible to identify the virus solely by relying on the type of symptoms displayed by the plant.

Different diagnostic methods may be used for begomovirus detection in bean plants. Even though antibody-based tests such as ELISA (enzyme-linked immunosorbent assay) and immunostrip assays are readily available for many plant viruses, specific antibodies and serological tests are lacking for bean-infecting begomovirus identification. Nucleic acid-based technologies are highly accurate and sensitive and are widely used for the detection of bean-infecting begomoviruses. BGYMV and BGMV were cloned and sequenced in the early 1990s, and the availability of genetic information of these and other begomoviruses allowed for the quick development of tests based on DNA molecular hybridization and polymerase chain reaction (PCR). Dot-blot and tissue blot are the most used assay formats in hybridization tests. Cloned viruses or virus genome fragments are used as probes in the hybridization tests, and the probe can be tailored to be a broad-spectrum probe and recognize several viruses or to be specific for a given virus, hybridizing only to that virus. Typically, a mixture of DNA-A components from different begomoviruses is used as a general probe under low stringency hybridization conditions, and the common region or a hypervariable fragment of the DNA-B of a particular bean-infecting begomovirus is used as a specific probe under high stringency hybridization conditions.

Currently, PCR is the most popular technique for the detection of bean-infecting begomoviruses due to its speed, sensitivity and accuracy. Different PCR set-ups, depending on the primers used, will provide general begomovirus detection or specific virus diagnosis. Usually, as a first step in identifying if a begomovirus is infecting a bean plant, very robust and effective universal degenerate primers designed in 1993 by M.R. Rojas and D. Maxwell at the University of Wisconsin are still used. Then, the amplicon is sequenced, permitting the initial identification of the begomovirus. Subsequently, back-to-back primers can be designed to recover the complete virus genome by inverse PCR for sequencing and definitive taxonomic classification. An additional set of specific primers can be designed to amplify part of the virus genome for specific diagnosis of that particular begomovirus in the samples.

More recently, alternative nucleic-acid based techniques that use isothermal amplification have been developed and are also employed for the identification of bean-infecting begomoviruses. RCA (rolling-circle amplification) uses random primers and a DNA polymerase with strand displacement properties, favoring ssDNA amplification into double-stranded products in a non-specific manner. RCA products can be cloned and sequenced allowing the identification and study of unknown viruses from symptomatic or asymptomatic samples. RCA is also valuable in discovering multiple virus infections in plants. Digestion of RCA products with restriction endonucleases and analysis of the restriction fragment length polymorphisms (RFLP) allows for the identification of mixed infections. Other diagnostic tools using isothermal amplification include loop-mediated isothermal amplification (LAMP) and recombinase polymerase amplification (RPL) assays. Protocols for LAMP and RPL are currently being developed for begomovirus diagnostics, and only RPL has been applied so far for BGYMV detection. However, these methods have great potential since they are sensitive, can use crude extracts and may be implemented to be used in the field.

High-throughput sequencing technologies (HTS), also known as next generation sequencing (NGS), have greatly advanced the detection and discovery of plant viruses. HTS coupled with appropriate bioinformatics is a very sensitive tool, having the potential to detect the whole virome of a sample, including known and unknown viruses. Hence, HTS has been considered an attractive alternative for diagnostic virology. For the identification of begomoviruses, diverse types of nucleic acid templates may be used as starting material in the sequencing process including RCA products, double-stranded RNA and small RNAs. The two latter ones enable the simultaneous detection of viruses with DNA and RNA genomes belonging to different genera and families, revealing complex multiple infections. Several HTS sequencing platforms are commercially available. However, the costs are still high for routine diagnosis.

Management

Bean golden mosaic disease is very challenging to control and manage. The disease occurs and is a serious problem in the tropical and subtropical regions of the Americas. These areas are also zones where the whitefly vector thrives, colonizing, besides common bean, other crops such as soybean, tomato, peppers, cucurbits, cotton, and numerous non-cultivated plants, which sometimes can act as virus reservoirs. Because these crops may be present in the field year-round, high populations of the whitefly are built and migrate to newly planted bean fields.

Chemical control using insecticides is the most used approach to control the whitefly vector and hence the infection caused by BGMV and BGYMV. However, the use of insecticides is not always efficient. Several types of molecules with different mechanism of action exist including nicotinoids and insect growth regulators. The over-employment of a determined insecticide chemistry over time may lead to the selection of resistant whitefly populations shortening the useful life of insecticides and, as a consequence, limiting the usefulness of chemical control. Thus, the alternation of products with distinct active ingredients should be implemented to preclude or delay resistance buildup. Severe epidemics and high yield losses are mainly recorded in the dry season when whitefly populations are high and may transmit begomoviruses to beans in the early phase of the cycle when the plants are young. To try to avoid serious yield reduction, a common practice is to treat the seeds and spray the fields with insecticide five to six times starting ten days after emergence, and then every five days until the plants are 40 days old. This type of schedule aims to control both adults and nymph stages, and as the whitefly population decreases, their migration to newly planted fields also tends to reduce. This scheme should take into consideration the insecticides' characteristics and are not appropriate for those that have longer residual activity.

Due to the limitations to the use of insecticides regarding the development of resistance in the whiteflies and environmental concerns, one of the best and sustainable options is the use of resistant cultivars. Many institutions throughout the Americas have dedicated great efforts in research programs focusing on breeding beans for resistance to golden mosaic disease. Screening attempts to identify common bean germplasm with disease immunity were unsuccessful. Thousands of bean accessions were evaluated under BGYMV and BGMV infection, and not a single genotype with full immunity was found. Some black-seeded genotypes displayed partial resistance or tolerance to BGYMV, and crosses between these genotypes rendered several lines denominated DOR that were released and cultivated, for example, in Guatemala. Further screening led to the selection of additional golden mosaic-resistant bean types with different seed colors. Genetic studies identified a few genes associated with the resistance in the different genotypes (*Bgp*, *bgm1* and *bgm2*). Pyramiding different genes into breeding lines allowed for the achievement of higher and more adequate levels of resistance and the introgression of these genes into resistant varieties. Cultivars with resistance to BGYMV were released in Honduras, Nicaragua, El Salvador, Costa Rica, Puerto Rico and Southern Florida with good acceptance by farmers.

Breeding for resistance to BGMV initiated in the 1970s in Brazil. Surveys for resistant genotypes and breeding efforts rendered bean lines with low levels of resistance that was controlled by polygenic and quantitative factors, and though a few cultivars with enhanced resistance were released, the resistance was not satisfactory under moderate to high BGMV incidence levels.

Because there were no good resistance sources to be exploited, bean improvement programs by crossing and selection of desired superior genotypes were unproductive in Brazil (the resistant cultivars planted in other Latin American countries are of different seed types which are poorly accepted by consumers in Brazil). Therefore, an alternative biotechnological approach was used to achieve BGMV resistance. The RNAi technology was explored to generate a transgenic bean line transformed with an intron-hairpin construction harboring a fragment of the BGMV *Rep* gene that expresses a *Rep*-derived double-stranded RNA and activates the RNA silencing mechanism in the plant. In this approach, the transgenic plant produces small interfering RNAs that induce the degradation of the BGMV-derived *Rep* mRNA, halting virus replication and disease progression. The transgenic line Embrapa 5.1 proved to be immune to BGMV, and after extensive risk assessment studies, this line was approved in 2011 by the Brazilian Biosafety Committee (CTNBio) for cultivation and human consumption in the country. The Embrapa 5.1 line was crossed with 'Carioca' type beans (the most widely consumed in Brazil), originating the cultivar BRS FC401 RMD which was tested in different environments, holding the resistance in the field since 2012. Even under high virus pressure, no symptoms or virus replication have been observed. BRS FC401 RMD is expected to be released for commercial production in 2020 and is recommended for cultivation in Central Brazil. It is important to point out that BRS FC401 RMD is most probably not resistant to other golden mosaic-inducing begomoviruses occurring in Brazil (MaYSV) or in other countries, and is not resistant to RNA viruses that infect beans such as bean rugose mosaic virus and cowpea chlorotic mottle virus. Hence, other measures still have to be employed to control those viruses.

Cultural practices may play a role in controlling bean golden mosaic disease. These include the sanitation of the field after harvest to eliminate any infected plants that could act as virus sources for the next crop; the avoidance of successive and continuous cultivation of the same crop in the same area; and prevention of virus transmission by sowing the new crop when the vector population and begomovirus availability are low. One control measure that is contributing to the reduction of begomovirus-associated disease in beans is the adoption of a host-free period. The host-free period usually spans from four to eight weeks after harvesting, when beans are not allowed to be cultivated. This type of measure is employed on a regional basis. Indeed, a bean-free period of four weeks in some areas in Brazil contributed to the reduction of the use of insecticides to control whiteflies and succeeded in reducing the losses due to BGMV infection. Similar success was achieved with an eight to twelve weeks of a bean-free period in the Dominican Republic in decreasing the incidence of BGYMV.

Glossary

Agroinoculation A method for inoculating plants with infectious clones of a virus inserted in between the T-DNA borders of a binary vector such that the T-DNA is inserted into the plant nucleus via a disarmed *Agrobacterium tumefaciens* strain.

Curly top disease A viral disease of plants characterized by stunting, up or downward curling and distortion of leaves, vein swelling, enations and purpling; the disease can be caused by genetically diverse geminiviruses, including *Beet curly top virus*.

Enation Virus-induced outgrowth from leaves (typically veins) or other plant tissues.

Endoreduplication DNA replication in the absence of cell division.

Etiology The cause of a disease.

Hemolymph The insect circulatory system.

Hyperplasia Unregulated cell division.

Hypertrophy Cell enlargement resulting from abnormal increase in cell size.

Non-propagative transmission Virus transmission mode in which the virus does not replicate in the vector.

Phloem-limited virus A virus that only infects cells and tissues of the phloem.

RFLP Restriction fragment length polymorphism, a molecular tool for fingerprinting and identifying DNA viruses.

Steckling A small plant composed mostly of the root of a biennial crop plant (e.g., carrot or sugar beet) that is usually exhumed, stored during the winter and replanted the next season for seed production.

Transovarial transmission Transmission of a virus vertically, through the insect egg.

Viruliferous The condition in which an insect vector is carrying a virus and can transmit the virus to an uninfected plant.

Introduction

Beet curly top virus (BCTV) is the type species of the genus *Curtovirus*, family *Geminiviridae*. Like all members of this family, BCTV has twinned quasi-icosahedral virions that measure $\sim 18 \times 30$ nm and a circular single-stranded DNA genome. BCTV is a phloem-limited virus that is transmitted by the beet leafhopper (BLH; *Circulifer tenellus* (Baker) (Homoptera: *Cicadellidae*) (Fig. 1(A)), and causes curly top disease of several economically important crops including common bean, pepper, sugar beet and tomato (e.g., Fig. 1(B–F)) in the western USA, north-central Mexico and countries of the Mediterranean Basin and the Middle East (e.g., Iran and Turkey), where it can cause substantial economic losses. Disease outbreaks are driven by populations of the beet leafhopper vector and favorable environmental conditions. In 2013, the disease caused an estimated US\$100 million loss to the California processing tomato industry. Research on various aspects of the virus has added important fundamental knowledge about geminiviruses and the complex epidemiology of plant viruses transmitted by insect vectors. BCTV and the beet leafhopper vector represent an early example of the introduction of an exotic virus-vector combination into a new geographic region, the New World (NW) through movement of plant materials (sugar beet roots and stecklings) by humans. The BCTV genome sequence provided early evidence of the important role of recombination in viral evolution. Studies of the etiology of curly top disease in different geographic regions revealed that this disease is caused by multiple genetically distinct geminiviruses. Curly top disease also serves as a success story for how the development and implementation of resistant varieties and other management strategies saved the sugar beet industry from economic collapse. Finally, the BCTV-BLH vector system may lead to the identification of the elusive receptor(s) involved in the persistent circulative transmission of plant viruses by their insect vectors.

History

The first reports of curly top disease were from sugar beet fields in the western USA in 1888. Along with the establishment and rapid growth of the sugar beet industry in this region (e.g., states of California, Idaho and Utah), came widespread and damaging outbreaks of curly top disease of sugar beet and other crops such as common bean, squash and tomato. Outbreaks of curly top disease caused substantial yield losses to sugar beet production in the western USA from ~ 1920 –1940 and the disease became a limiting factor in sugar beet production during this time, causing abandonment of major production areas and the closing of sugar

Fig. 1 (A) Beet leafhopper (*Circulifer tenellus*) feeding on a vein on the abaxial side of a sugar beet leaf infected with *Beet curly top virus* (BCTV); (B) Portion of a tomato field with plants infected with BCTV, showing severe stunting and yellowing and poor stand due to plants that have died from the disease; (C) BCTV-infected tomato plant showing typical symptoms of curly top including stunting, upward leaf curling and yellowing; (D) Close-up of foliar symptoms of curly top disease in tomato showing upward rolling, dull green to yellow coloration and swollen and purple veins; (E) BCTV-infected sugar beet plant showing foliar symptoms of curly top on the leaves, including yellowing, crinkling, and upward curling; (F) Abaxial side of leaves of a BCTV-infected sugar beet plant showing swollen veins and enations associated with curly top disease; and inset showing darkening of vascular tissue in the root of a sugar beet plant infected with BCTV and showing curly top symptoms.

refineries. Subsequently, curly top-like diseases were reported to occur in western Canada, north-central Mexico, Brazil, Argentina, the Caribbean Basin, Turkey, and Iran. Here, it is important to note that molecular characterization of the causal agent of curly top disease from different geographical regions has revealed that these disease symptoms can be caused by multiple genetically distinct geminiviruses, including some that are not in the genus *Curtovirus*. Thus, symptoms alone are insufficient for diagnosis, and molecular tests (PCR and sequencing) are needed to confirm the identity of the causal agent.

An association between curly top disease and the beet leafhopper (**Fig. 1(A)**) was noted, and evidence that this insect was a vector of curly top disease was first presented in 1909. These phloem feeding insects acquired and transmitted the causal agent of curly top rapidly (minutes), although longer periods of acquisition were needed for high rates of transmission. The curly top agent also persisted within the leafhopper vector, but it did not appear to replicate in the insect. Although the leafhopper transmission properties supported a viral etiology for curly top disease, the low level of accumulation (viral titer) of the causal agent in plants made purification difficult. This was mostly due to the virus exclusively infecting cells of the phloem. It was not until the 1970s that dimeric or twinned virus-like particles, measuring ~20–30 nm, were purified from curly top-infected plants. This suggested that the causal agent of curly top might be a geminivirus, and further evidence came from the development of curly top symptoms in plants exposed to beet leafhoppers that had fed on purified preparations of the twinned virus-like particles. These results indicated that curly top disease was caused by a geminivirus, which was named *Beet curly top virus*.

The viral genomic DNA was eventually cloned from DNA isolated from leaves of sugar beet plants with curly top disease symptoms, and the DNA sequence was determined in 1986. Analysis of the BCTV sequence confirmed that BCTV was a geminivirus, and also revealed that the virus has a hybrid genome composed of complementary-sense genes having greatest identities with those of whitefly-transmitted geminiviruses (genus *Begomovirus*) and virion-sense genes having highest identities with those of leafhopper-transmitted geminiviruses (genus *Mastrevirus*) (**Fig. 2**). This clearly indicated that recombination played a major role in the emergence of BCTV. The cloned genomic DNA of BCTV induced curly top symptoms in sugar beet plants, when delivered by agroinoculation, thereby fulfilling Koch's postulates for curly top disease. Progeny virions derived from the infectious BCTV clone were transmitted by beet leafhoppers and subsequent development of curly top symptoms in inoculated sugar beet plants confirmed leafhopper transmissibility of BCTV.

Classification and Nomenclature

Early investigations of host range, symptoms, and virulence suggested that curly top disease in the western USA was caused by a complex of viral strains/species. To some extent, this hypothesis has been supported by molecular (RFLP and sequencing) studies showing genetic diversity among the viruses causing curly top disease. In the western USA three strains were characterized based on

Fig. 2 The genome organization of *Beet curly top virus* (BCTV). The position and orientation of virion-sense (V) and complementary-sense (C) open reading frames (ORFs) are shown in relation to the intergenic region (IR) that contains the invariant nonanucleotide motif TAATATTAC and iterons (repeated sequences underlined with arrows) involved in replication-associated protein (Rep) recognition and the initiation of viral DNA replication. The recombinant nature of the BCTV genome is shown with the virion-sense genes having highest identities with those of leafhopper-transmitted geminiviruses (mastreviruses) shown in orange, and the complementary-sense genes having highest identities with those of whitefly-transmitted geminiviruses (begomoviruses) shown in blue. CP, capsid protein; and REEn, replication enhancer protein.

^bStrain abbreviations: BCTV-Wor, BCTV-Worland; BCTV-Mld, BCTV-Mild; BCTV-Svr, BCTV-Severe; BCTV-SpCT, BCTV-spinach curly top; BCTV-PeCT, BCTV-pepper curly top; BCTV-PeYD, BCTV-pepper yellow dwarf; BCTV-CO, BCTV-Colorado; BCTV-LH71, BCTV-leafhopper71; BCTV-SvrPep, BCTV-severe pepper; BCTV-Kim1, BCTV-Kimberly1; BCTV-HRCT, BCTV-Horseradish curly top.

^cSpecies abbreviations: BMCTV, Beet mild curly top virus; BSCTV, Beet severe curly top virus; SpCTV, Spinach curly top virus; PeCTV, Pepper curly top virus; PeYDV, Pepper yellow dwarf virus; HrCTV, Horseradish curly top virus; and SpSCTV, Spinach severe curly top virus.

molecular and biological properties: BCTV-Cal/Logan, BCTV-Worland and BCTV-CFH, with the strain designation generally reflecting the geographic origin of these strains (Table 1). Another strain was recovered from a horseradish plant with brittle root disease in Illinois and was designated BCTV-HRCT. The first strain for which the complete sequence was determined was BCTV-Cal/Logan in 1986. As sequences of more BCTV strains and putative new curtoviruses became available, additional genetic diversity as well as differences in biological properties (e.g., host range, symptomatology in sugar beet plants, and transreplication) were revealed. The taxonomy of viruses causing curly top disease is now largely based on genome properties, e.g., genome-wide sequence identities, along with some consideration of biological properties of the viruses.

At the same time, the properties used to classify geminiviruses were also being defined and used to establish genera within the family *Geminiviridae*. The key properties that were used to classify geminiviruses were: genome organization, DNA sequence relationships, type of insect vector and host range of the virus. The viruses causing curly top disease in the western USA were placed into the genus *Curtovirus* (name derived from *curly top*) based upon (1) having a monopartite genome, (2) a high degree of sequence identity among members of the genus and divergence from sequences of species of other genera, (3) being transmitted by the beet leafhopper and (4) infecting dicotyledonous plants. There were originally four geminivirus genera: *Curtovirus*, *Begomovirus* (whitefly-transmitted and dicot-infecting),

Fig. 3 Phylogenetic network generated with the complete genomes of 104 isolates of *Beet curly top virus* (BCTV) and illustrating the grouping of the isolates into the eleven recognized strains of the virus and their relationships with one another. The other two species in the genus *Curtovirus*, *Spinach severe curly top virus* (SpSCTV) and *Horseradish curly top virus* (HrCTV), were used as out-groups. The *P*-value of the pairwise homoplasy index (PHI) statistical test of recombination is shown on the bottom of the network.

Mastrevirus (leafhopper-transmitted and mostly monocot-infecting) and *Topocuvirus* (treehopper-transmitted and dicot-infecting). However, with the advent of inexpensive DNA sequencing and rapid methods for the amplification and cloning of geminivirus genomes, new types of geminiviruses have been identified and characterized. Thus, the family is now subdivided into nine genera with five new genera recently established: *Eragrovirus*, *Capulavirus*, *Grablovirus*, *Becurtovirus*, and *Turncurtovirus*. Here, it is important to note that the genera *Becurtovirus* and *Turncurtovirus* contain viruses, some of which are transmitted by the leafhopper *C. haematoceps*, that cause curly top-like disease symptoms in sugar beet and other crops. Thus, curly top disease symptoms can be caused by multiple genetically divergent geminiviruses from three genera. Therefore, molecular methods are needed to conclusively identify the virus(es) associated with the disease in a given geographical region.

The use of DNA sequences for classification and phylogenetic analysis of geminiviruses has provided important insight into viral evolution and the relationships among members of this large family of viruses. However, the relationships among some geminiviruses have been complicated by extensive recombination, especially those in the genera *Begomovirus* and *Curtovirus*. Thus, because recombination has played a major role in their evolution, it can be difficult to establish an exact lineage for some viruses, i.e., whether it represents the parent or progeny of a recombination event. Another important issue is where to establish the cut-off values for establishing species, strain and isolate relationships in different genera. With the large number of sequences now available, these values are typically established based upon genome-wide pairwise identities.

The original species demarcation value for curtoviruses was 89% identity, i.e., sequences having identities >89% to a known species represent isolates or strains of that species. This was the same species demarcation value used for begomoviruses. Other criteria that were considered in establishing curtovirus species were (1) lack of transreplication of known species mediated by the Replication-associated protein (Rep), (2) serological properties, and (3) biological properties (e.g., symptoms in sugar beet). Based upon these criteria, three BCTV strains were elevated to species in 1998: *Beet curly top virus* (type species, BCTV-Cal/Logan strain), *Beet mild curly top virus* (BCTV-Worland strain [BCTV-Wor]) and *Beet severe curly top virus* (BCTV-CFH strain) (Table 1). In addition, BCTV-HrCT was elevated to species (*Horseradish curly top virus*, HrCTV), as were at least five other curtoviruses associated with curly top disease in various crops (formally or informally). However, in 2014, the taxonomy of curtoviruses was revisited and, based upon genome-wide pairwise identities of all available curtovirus sequences, a new species demarcation value of 77% identity or greater was established, with little or no consideration of other properties. Based upon these new criteria, the genus *Curtovirus* currently includes only three species: the type species BCTV, HrCTV and the more recently described *Spinach severe curly top virus* (SpSCTV) (Fig. 3 and Table 1). The species BCTV is comprised of 11 recognized strains, which share <94% identity and, in some cases have different serological and biological properties (Fig. 3 and Table 1). Like BCTV-Cal/Logan, most of the recognized strains of BCTV have recombinant genomes (e.g., Fig. 4). HrCTV and SpSCTV also have recombinant genomes and lack a C3 ORF. The latter two species appear to have limited distribution and minimal economic impact, perhaps reflecting reduced fitness due to these genomic properties. For example, HrCTV was isolated in 1990 from a horseradish plant with brittle root disease in Illinois, USA, but Koch's postulates were not fulfilled for this disease nor has the virus emerged as a pathogen of economic importance. However, as the genomes of HrCTV and SpSCTV are composed mostly of curtovirus sequences and are well below the 77% species demarcation threshold, they clearly represent distinct curtovirus species.

Fig. 4 Similarity plot analysis of complete genome sequences of three strains of *Beet curly top virus* (BCTV): BCTV-CO, BCTV-LH71 and BCTV-PeCT. Bootscan analysis was performed with a sliding window of 200 nucleotides and step size of 20 nucleotides with Neighbor-Joining phylogenetic trees with 100 bootstrap replicates inferred in each case. This analysis provides a schematic representation of the recombination profile of each of these strains (query) as revealed by comparisons with other BCTV sequences in the NCBI database. The horizontal arrows on the top indicate the position of the open reading frames (ORFs) encoded by the BCTV genome. LIR, left side of the intergenic region and RIR, right side of the intergenic region.

The Origin of BCTV and the Beet Leafhopper Vector: An Early Example of Global Transport of a Plant Pathogen and its Vector

Curly top disease continues to have the greatest economic impact on sugar beet and processing tomato production in the western USA. Soon after the disease became a major problem for sugar beet production, there were questions regarding the origin of BCTV and the beet leafhopper vector, i.e., were they indigenous to the NW or was one or both introduced from another region? Multiple lines of evidence suggest that BCTV originated in the OW and was introduced, along with the beet leafhopper, into the NW via movement of sugar beet propagative materials (e.g., roots and Stecklings) brought with settlers coming from the OW (e.g., Europe and the Mediterranean Basin). The evidence for the introduction of the beet leafhopper included (1) the presence of *C. tenellus* and its closest relative in the OW (Mediterranean Basin), (2) interbreeding between NW and OW beet leafhopper populations, and (3) transmission of the causal agent of curly top in the NW by beet leafhoppers from the OW. The origin of BCTV remained unclear as there were no reports of curly top disease in the OW. However, in 1955, curly top disease of sugar beet was reported from Turkey and, subsequently, from Iran. In 1998, an isolate of BCTV from sugar beet plants with curly top disease symptoms in Iran (BCTV-I) was reported to have a high level of nucleotide sequence identity with BCTV strains from the NW, including >98% identity with BCTV-CFH (now BCTV-Svr [US-SVR-Cfh]). Moreover, an infectious clone of BCTV-I induced symptoms in *N. benthamiana* and sugar beet that were indistinguishable from those induced by the infectious clone of BCTV-CFH. This suggested a common origin for BCTV in the NW and OW, though it did not resolve the origin of BCTV. Evidence for an OW origin of BCTV comes from (1) the high levels of resistance to curly top disease in wild beet species in the OW (where sugar beet originated), suggesting virus-host coevolution over a long period of time,

and (2) a portion of the recombinant genome of BCTV was derived from an OW leafhopper-vectored mastrevirus, consistent with emergence and evolution of BCTV in the OW. Although more BCTV genetic diversity has been documented in the NW, this could simply reflect the greater amount of research conducted on BCTV in the NW, or multiple introductions of BCTV strains from the OW and subsequent evolution mediated by mutation and recombination, which are facilitated during major curly top disease outbreaks. Taken together, these results support the hypotheses that both BCTV and the beet leafhopper vector originated in the OW and were introduced into the NW by the activities of humans. Unfortunately, the desert environment of the western USA was ideal for establishment of populations of beet leafhoppers and the associated BCTV.

Geographic and Seasonal Distribution

Curly top disease occurs widely throughout arid and semiarid regions of the western USA, where high populations of the beet leafhopper vector can occur. It is here that the epidemiology of the disease and the life cycle of the insect vector has been extensively investigated. At the end of the growing season (in the fall), adult female beet leafhoppers (some of which are viruliferous) migrate from agricultural fields to overwintering areas (e.g., foothills of mountain ranges located on the western side of the Central Valley of California), where they survive on perennial weeds. In late winter to early spring, these females lay eggs into stems and petioles of perennial and annual weeds. The resulting nymphs and adults of this new generation acquire BCTV as they feed in the phloem of infected weed reservoir hosts, most of which show few or no symptoms. Initially, the virus and vector survive on perennial weeds such as Russian thistle (*Salsola* sp.) and saltbush (*Atriplex* sp.), until winter rains lead to the emergence of annual weeds, such as filaree (*Erodium* sp.), peppergrass (*Lepidium* sp.) and plantain (*Plantago* sp.) on which the leafhoppers propagate. As these winter annuals become dry in mid- to late-spring, some combination of viruliferous and non-viruliferous adult beet leafhoppers migrate from the overwintering areas to agricultural areas (often valleys), where they transmit BCTV to crops including sugar beet (*Beta vulgaris*), tomato (*Solanum lycopersicum*), common bean (*Phaseolus vulgaris*), and pepper (*Capsicum annuum*), as well as to common agricultural weeds as they search for preferred hosts for reproduction. Depending on the geographic region, beet leafhoppers undergo 3–5 generations on weeds, such as wild mustards (*Brassica* sp.), London rocket (*Sisymbrium irio*), Shepherd's purse (*Capsella bursa-pastoris*) and goosefoot (*Chenopodium* sp.). As crops are harvested and summer annuals dry in the fall, some combination of viruliferous and non-viruliferous adult female leafhoppers migrate from agricultural areas back to their overwintering areas.

Changes in BCTV Strain Prevalence

BCTV strain diversity was investigated in samples of sugar beets with curly top disease collected from commercial fields in Texas in 1994 with restriction fragment length polymorphism (RFLP) analysis. The predominant strains were BCTV-Wor (previously BMCTV) and BCTV-Svr [US-SVR-Cfh] (previously BSCTV), with no detection of BCTV-Cal/Logan (type species). BCTV-Wor and BCTV-Svr were also the predominant strains detected in a more comprehensive survey of sugar beets with curly top symptoms collected from California, Colorado, Idaho, New Mexico, Oregon, Texas, Washington, and Wyoming in 1995. In a survey of tomato plants with curly top symptoms, beet leafhoppers and weed species in the Central Valley of California conducted between 2002 and 2008, BCTV-Wor and BCTV-Svr were prevalent, although BCTV-Cal/Logan was detected in a small number of leafhopper samples. Another survey of BCTV strains associated with curly top of sugar beet in the western USA was conducted from 2006–2007 and, again, BCTV-Wor and BCTV-Svr were prevalent, although a small number of plants from Idaho and Oregon were infected with BCTV-Cal/Logan. In these surveys, it was not uncommon to find plants infected with genotypic variants of these strains or co-infections of more than one strain.

Interestingly, a major shift in the BCTV population structure has been detected in recent years in sugar beet and processing tomato samples from the Pacific Northwest and the Central Valley of California, respectively. A survey of sugar beets with curly top symptoms from Idaho and Oregon was conducted between 2012 and 2015 in response to concerns about increased curly top disease severity. The results revealed that (1) BCTV-CO and BCTV-Wor had become the prevalent strains, (2) there was a re-emergence of BCTV-Cal/Logan (30% of isolates detected) and (3) there was a decline in the prevalence of BCTV-Svr. Although BCTV-CO and BCTV-Wor are closely related (Figs. 3 and 4), they were differentiated by whole genome sequencing. Following the 2013 curly top outbreak in processing tomatoes in the Central Valley of California (where there is currently little or no sugar beet production), surveys of tomato plants with curly top symptoms and symptomless weeds in the foothills conducted from 2014 to 2018 revealed that BCTV-CO and BCTV-LH71, a new recombinant strain initially identified from viruliferous leafhoppers (Fig. 4) were predominant, rather than BCTV-Wor and BCTV-Svr. This was particularly true with samples of tomatoes with curly top symptoms, whereas more strain diversity was detected in the weeds. Interestingly, in crop and weed samples from the Imperial Valley of California, where sugar beets are still grown, more BCTV-Svr was detected. In addition, two other BCTV strains were detected in pepper and tomato samples collected in California in 2014–2018, BCTV-spinach curly top (BCTV-SpCT) and BCTV-pepper curly top (BCTV-PeCT) (Table 1). Together, these results revealed a dramatic shift in strain prevalence in two different crops in two geographical regions, and the emergence of BCTV-CO as a major strain in both regions. Although the basis for this population shift in BCTV strains remains unknown, it may reflect changes in cropping patterns or in the predominant weed reservoirs surrounding agricultural fields and selection of more virulent or fit strains. For example, BCTV-CO and BCTV-LH71 appear to be better adapted to tomato.

Genome Organization and Gene Expression

Like all geminiviruses, BCTV has a genome of circular single-stranded DNA (ssDNA) that is encapsidated in twinned (geminate) quasi-icosahedral particles measuring approximately 18×30 nm. The BCTV genome is composed of a single genomic DNA of ~ 3000 nt that encodes seven genes distributed between the virion-sense (V) and complementary-sense (C) strands (also referred to as rightward [R] and leftward [L] strands in the literature), separated by an intergenic region (IR) of ~ 300 nt, which contains the origin of replication (Fig. 2). A nonanucleotide motif (TAATATTAC), which is highly conserved among all geminiviruses, is located within the IR and lies in between inverted repeat sequences with the potential to form a stem-loop structure. Short repeat sequences, termed iterons, are upstream of the stem-loop (Fig. 2). The complementary-sense genes encode the Rep protein (ORF C1) that is required for viral DNA replication, the replication-enhancer REn (ORF C3), and two proteins that contribute to viral pathogenicity (ORFs C2 and C4). The virion-sense gene products include the capsid protein (CP, ORF V1) and proteins involved in the regulation of the relative levels of viral ssDNA and double-stranded DNA (dsDNA) (ORF V2) and virus movement (ORF V3) (Fig. 2). The complementary-sense gene products are required during the early stages of infection, whereas the virion-sense ORFs encode proteins that are required later in infection, as the virus shifts to virion formation and movement within the plant.

The identification of BCTV virion- and complementary-sense transcripts is consistent with a bidirectional transcription strategy that, along with overlapping genes (in different frames), maximizes the number of genes encoded by a small genome (Fig. 2). The two most abundant complementary-sense transcripts are similar to their begomovirus counterparts, with the larger transcript mapping across all four ORFs and the smaller transcript across ORFs C2 and C3. Overall, the most abundant transcripts mapped across the virion-sense ORFs and downstream of two consensus eukaryotic promoter sequences. The most abundant transcript mapped to the ORFs V2 and V3, whereas a less abundant transcript mapped to ORF V1. Precisely how the viral proteins are translated from these transcripts is not yet understood, but the overlapping nature of both the virion-sense and complementary-sense ORFs may provide temporal control during the infection cycle.

Replication

The virion-sense ssDNA carried in the BCTV virion must gain access to the nucleus of phloem cells (e.g., companion and phloem parenchyma), where replication of viral DNA occurs. It is not known if virions or viral DNA released from disassembled virions enters the nucleus following introduction of virions by the beet leafhopper vector. Once in the nucleus, the virion-sense ssDNA is converted into dsDNA, mediated by host-derived short DNAs as primers and host DNA polymerases (note that geminiviruses do not encode a DNA polymerase). Fractionation of viral DNA forms by a combination of chromatography and two-dimensional gel electrophoresis has identified BCTV intermediates consistent with both rolling-circle and recombination-dependent replication strategies. During rolling-circle replication, Rep interacts with the iterons located in the IR and introduces a nick into the virion-sense strand of the dsDNA within the nonanucleotide motif (TAATATTAC). By analogy with the replication strategy of begomoviruses, Rep then forms a covalent bond with the 5' terminus of the nicked virion-sense strand, whereas the 3' terminus must be extended by a host DNA polymerase. The full-length nascent strand is nicked and ligated by Rep to produce a genomic circular ssDNA that either re-enters the replication cycle (i.e., be converted to dsDNA early in infection) or is encapsidated to form virions (later in infection).

The interaction between Rep and the origin of replication is defined by the amino acid sequence of the N-terminal region of Rep and the iteron sequences of the origin of replication. This interaction is highly specific and determines whether transreplication occurs between strains or species (i.e., the Rep of one strain/species mediates the replication of another strain/species). For example, the Rep of the BCTV-Cal/Logan strain functionally interacts with its own iteron, GGAGTATTGGAGT (iteron underlined) (Fig. 2), but not with those of BCTV-Wor [US-Mld-Wor], GGTGCTATCGGAG, and BCTV-Svr [US-SVR-Cfh], GGTGCTTTGGGTG. Conversely, the Rep proteins of BCTV-Wor and BCTV-Svr do not functionally interact with the iterons of BCTV-Cal/Logan, whereas the BCTV-Wor and BCTV-Svr iterons are sufficiently similar to allow functional interaction with the Rep proteins of these strains and, thus, transreplication. Comparison of Rep N-terminal amino acid sequences has revealed residues conserved between BCTV-Wor and BCTV-Svr and that differ from those of the BCTV-Cal/Logan Rep. These residues, referred to as the iteron recognition domain (IRD), are involved in iteron recognition. Whereas replication incompatibility between cis- and trans-acting elements may be considered to maintain the integrity of a particular species, this constraint can be overcome by a recombination event in which the functional module comprising the 5' terminus of the Rep ORF and the origin of replication is exchanged between incompatible viruses.

Indeed, in addition to mediating the emergence of the hybrid genome of the BCTV progenitor, recombination also has played a major role in the evolution and emergence of other BCTV strains, including BCTV-CO, BCTV-LH71, and BCTV-PeCT (Fig. 4). This is mediated by recombination-dependent replication, which typically occurs later in the infection cycle compared with rolling-circle replication, possibly due to higher DNA concentrations and the presence of ss- and dsDNA forms that mediate template switching and recombination. It remains to be established which, if any, viral proteins contribute to this process, although it is possible that Rep helicase activity could participate in both replication strategies. Additionally, the nick site for rolling-circle replication has been shown to be a recombinational hot spot. Thus, recombination-dependent replication likely explains the high frequency of recombinant geminiviruses.

Subgenomic-sized defective viral DNAs of diverse size (ranging from 800 to 1800 nt) and complexity are rapidly produced from the cloned BCTV genomic DNA in sugar beet, tomato, and *N. benthamiana*. Deletions occur within all ORFs and only the IR

sequence is conserved, consistent with its participation in viral DNA replication. BCTV-infected sugar beet plants grown in fields frequently contains such defective DNAs, indicating that they are also produced under natural conditions. They occur as both single- and double-stranded DNA forms but it is not known if they are encapsidated or have the ability to move systemically in the plant. However, in view of their rapid appearance, it is likely that they are produced *de novo* in every infected cell. Short repeat sequences of 2–6 nt at the deletion boundaries may specify the deletion endpoints and suggest that the defective DNAs are produced by recombination. These subgenomic-sized DNAs can interfere with infection, presumably by competing for a limited amount of Rep, and may have a biological role in modulating pathogenicity of the helper virus to encourage leafhopper feeding and virus transmission.

Virus Movement

The CP is a multifunctional protein that is targeted to the nucleus, probably via one or more nuclear localization signals (NLSs) in the N-terminus, where virion formation and accumulation occurs. In transient expression experiments in protoplasts and bombarded common bean hypocotyl tissues, a BCTV-Wor [US-Mld-Wor4] (previously BMCTV) CP-GFP fusion protein was targeted to the nucleus and formed ring-like structures, reminiscent of fibrillary rings observed in nuclei of BCTV-infected cells in ultra-structural studies. Late in infection, virions and viral nucleic acids form large aggregates or inclusion bodies in nuclei of BCTV-infected phloem cells.

The BCTV CP is essential for systemic infection and leafhopper transmission. BCTV-Wor [US-Mld-Wor4] CP alanine scanning mutants that retain the ability to form virions (mainly N-terminal mutations) were generally able to produce a systemic infection and were leafhopper-transmissible, whereas those unable to form virions (mainly C-terminal mutations) were not, despite being competent for replication. Thus, these results suggest that the C-terminal amino acids of the CP play an important role in virion assembly, and that long-distance movement of BCTV (in the plant) occurs in the form of virions, which is consistent with the observation of virus-like particles in phloem sap exudates of leaves of *Amsinckia douglasiana* plants with curly top symptoms.

ORF V2 mutants accumulate high levels of dsDNA and greatly reduced levels of ssDNA compared with the wild-type virus, implicating the V2 protein in the regulation of the levels of these viral DNA forms. However, the V2 protein does not have a typical NLS, and in transient expression experiments in protoplasts and bombarded hypocotyl tissues, a V2-GFP fusion protein was localized to the endoplasmic reticulum (ER), including having a perinuclear distribution. If the function of the V2 protein is to ensure that ssDNA is available in sufficient amounts for encapsidation and systemic movement late in infection, this may involve V2-mediated nucleocytoplasmic transport of an infectious form of the virus, e.g., virions or some other nucleoprotein complex. The possibility of an infectious non-virion form of BCTV was suggested based on results with alanine scanning mutant CP 49–51, which infected and caused curly top symptoms in *N. benthamiana* plants, but did not form virions and was not leafhopper transmissible.

ORF V3 mutants are competent for replication but produce only sporadic and symptomless infections with low levels of viral DNA in sugar beet and *N. benthamiana* plants, suggesting a role for the V3 protein in virus movement. In transient expression experiments in protoplasts and hypocotyl tissues, V3-GFP initially localized to the nuclear periphery and ER, similar to V2-GFP. However, V3-GFP subsequently was localized to motile ER-derived vesicle-like structures, which were observed around the nucleus, in the cytoplasm and at the cell periphery. It is tempting to speculate that this represents a transport mechanism, possibly delivering an infectious form of the virus to the cell periphery and plasmodesmata for limited cell-to-cell movement.

Finally, it is important to consider how the virions are acquired by leafhoppers during the feeding process. Although virions seem to be the main form in which BCTV moves in the phloem, it is not known if this occurs as individual virion particles or aggregates (e.g., intact or degraded parts of inclusion bodies). It is also not clear how virions enter the phloem. One hypothesis involves the collapse and death of BCTV-infected phloem cells and the release of cell contents, including inclusion bodies, into the developing phloem sieve elements, possibly in the shoot apex. These virions would then be available for acquisition by beet leafhoppers or long-distance movement in the phloem in a source-to-sink manner to infect new protophloem and other phloem cells in the newly developing root and shoot apices. In this ‘wave of infection’ model, the virus is continually infecting and colonizing the nucleate phloem progenitor cells in newly developing shoots.

Host Range and Pathogenesis

In contrast to most other geminiviruses that typically have a narrow host range, BCTV is reported to have an extremely wide host range, including over 300 species of dicotyledonous plants in 44 families, including members of the Chenopodiaceae, Compositae, Cruciferae, Leguminosae, and Solanaceae. Here, it is worth noting that the BCTV host range was established from early observations of diseased plants of undefined etiology, when it was difficult to precisely identify the causal virus(es) involved. Therefore, the reported host range of BCTV should be confirmed.

However, using agroinoculation and leafhopper transmission of infectious clones and progeny virions, respectively, relatively wide host ranges (at least among crops) were demonstrated for BCTV-Wor, BCTV-Svr, BCTV-SpCT, BCTV-Mld, BCTV-CO and other strains. Furthermore, the curly top symptoms that developed in these plants were similar to those described in these crops in the

field. BCTV-infected crop plants also had high concentrations (titers) of virus. In contrast, non-cultivated plants such as weeds typically show few or no symptoms when infected by BCTV, and such plants often have lower levels of virus. However, BCTV infects a wide variety of annual and perennial weed species and at rates as high as 20% (in the foothills of California), which serve as reservoirs of the virus, especially in leafhopper breeding areas. Moreover, even though the levels of virus are low in most infected weeds, the feeding characteristics of the beet leafhopper allows for concentration of the virus in viruliferous insects.

The products of BCTV complementary-sense ORFs C2 and C4 have been associated with pathogenesis. ORF C2 mutants induce severe symptoms and accumulate to wild-type virus levels in sugar beet and *N. benthamiana*. However, plants infected with these mutants have a greater propensity for recovery from severe symptoms compared with those infected with wild-type virus, suggesting that the C2 protein suppresses a plant defense response. Consistent with this hypothesis, transgenic *N. benthamiana* and *N. tabacum* plants constitutively expressing the C2 protein exhibit enhanced susceptibility to BCTV infection, as revealed by a shorter latent period before symptom development. However, when infected with BCTV, these transgenic plants did not develop more severe symptoms or accumulate higher levels of viral DNA compared with non-transformed control plants. The transgenic plants were also more susceptible to the begomovirus *Tomato golden mosaic virus* (TGMV) and the unrelated RNA virus *Tobacco mosaic virus*, indicating that the C2 protein affects a nonspecific host defense response. Consistent with these observations, the C2 protein has been shown to suppress post-transcriptional gene silencing (PTGS) and transcriptional gene silencing (TGS) in *N. benthamiana*. In this respect, the BCTV C2 resembles the AC2 homolog in the begomovirus TGMV. However, the two proteins share only limited homology, and the BCTV C2 protein does not appear to have transcriptional activator activity for virion-sense gene expression as has been shown for TGMV AC2. Despite this divergence, both BCTV C2 and TGMV AC2 proteins bind to, and inactivate, adenosine kinase (ADK), an enzyme required for 5'-adenosine monophosphate (AMP) synthesis. ADK activity is also reduced in BCTV-infected plants and transgenic plants expressing C2 protein. Regulation of adenosine levels by ADK plays a key role in the control of intermediates required for methylation, which is the underlying mechanism of TGS and provides a possible link between C2 protein activity and suppression of TGS targeting the viral genome. Both BCTV C2 and TGMV AC2 proteins also bind to, and inhibit, sucrose non-fermenting 1 (SNF1)-related nucleoside kinase. Reduction of SNF1 protein kinase expression in *N. benthamiana* results in an enhanced susceptibility phenotype resembling that associated with the expression of C2 and AC2 proteins, whereas SNF1 overexpression produces plants with reduced symptom severity. This activity is not directly linked to silencing suppression, suggesting that C2 protein inhibition of SNF1 activity affects a different plant defense pathway. BCTV ORF C3 mutants produce severe symptoms and accumulate to wild-type levels in *Nicotiana benthamiana* plants, but they induce only mild symptoms and accumulate low levels of viral DNA in sugar beet plants. This suggests that the BCTV RE_n may enhance viral DNA replication in a host-dependent manner.

BCTV typically induces upward curling of the leaves (Fig. 1(B-F)) and clearing, enations and swelling of veins on the abaxial side of leaves, particularly in leaves of sugar beet plants (Fig. 1(F)). Although the phloem-limited virus cannot access the apical meristem, it is possible that BCTV exploits undifferentiated cambium cells in the vascular bundles or nucleate protophloem cells in the root and shoot apices, as shown for the begomovirus *Bean dwarf mosaic virus*. BCTV infected tissues exhibit hyperplasia and hypertrophy within the phloem and adjacent parenchyma, and the abnormally dividing cells differentiate into sieve element-like cells. In older infected tissues, the affected phloem cells eventually become necrotic and collapse. Pathogenic effects occur in developing tissues only after maturation of sieve elements, consistent with the virus moving from source to sink cells with the flow of photoassimilates, either to newly developing shoots or roots, depending on where the leafhopper introduced the virus to the plant (there can be large amounts of BCTV in roots). Infected sugar beet leaves accumulate enhanced levels of sucrose, attributed to impaired transport resulting from disruption of the phloem. This is associated with a reduction in chlorophyll content, reduced activity of key photosynthetic enzymes and a concomitant reduction in the rate of photosynthesis and altered turgor pressure that causes an increase in mesophyll cell size.

Geminiviruses are masters at manipulating the plant cell cycle to produce an environment suitable for their replication and spread. This is achieved by the interaction of Rep with the plant homolog of retinoblastoma-related tumor-suppressor protein (pRBR), which relieves the constraint imposed by pRBR binding to the E2F transcription factor and allows the expression of E2F-responsive genes. BCTV infection induces cell division within vascular tissues, attributed to the action of the C4 protein. Sugar beet infected with ORF C4 mutants remain asymptomatic and *N. benthamiana* plants show an altered phenotype; neither host develops hyperplasia of the phloem or enations. Furthermore, transgenic *N. benthamiana* plants expressing C4 protein show abnormal plant development and tumorigenic growths. Consistent with this phenotype, C4 protein interacts with BIN2, a negative regulator of transcription factors in the brassinosteroid signaling pathway that controls cell division and tissue development. The reasons for the induction of cell division are not clear, particularly as the hyperplastic tissues often do not contain detectable levels of virus. However, it is likely that it does provide additional nucleate cells that can be infected, via cell division or a yet to be determined means of cell-to-cell movement, and produce virions that can be released into sieve elements for long-distance movement or acquisition by the beet leafhopper vector.

The host range of BCTV includes *Arabidopsis thaliana*, which represents an important resource for the study of virus-host interactions. Most susceptible ecotypes become stunted and develop enations on infected leaves. The Sei-O ecotype is hypersusceptible to BCTV-Svr and develops callus-like structures containing high levels of the virus, suggesting a virus-induced hormonal imbalance. Symptom development correlates with enhanced expression of the cell cycle gene *cdc2* and small auxin-upregulated RNA gene (*saur*). Hence, disruption of the phloem in infected tissues may affect auxin transport, causing localized increases that result in cell proliferation.

Transmission of BCTV by the Beet Leafhopper Vector

In nature, BCTV is transmitted, plant-to-plant, exclusively by the beet leafhopper (*C. tenellus*, Fig. 1(A)). BCTV is not transmitted by contact or mechanically (sap inoculation) and is not believed to be seed-transmitted, although seed transmission of BCTV in petunia has been reported. A search for additional insect vectors in the NW was unsuccessful, which indicated a high degree of specificity in the association of the curly top agent and the beet leafhopper. However, other species of *Circulifer* from the OW can vector BCTV, and *C. opacipennis* was reported to vector the curly top agent in the Mediterranean Basin. There is no evidence for strain specificity in transmission of BCTV by *C. tenellus*, and all strains tested to date have been leafhopper-transmissible. The mode of transmission is persistent circulative, and there is no evidence that BCTV replicates in the insect vector. The beet leafhopper is an efficient vector of BCTV and rapidly acquires the virus (in minutes) from the phloem of infected plants. Being a mobile, polyphagous phloem-feeding insect makes the beet leafhopper an ideal vector for BCTV. The leafhopper also prefers to feed from veins on the abaxial side of young- to medium-aged leaves, including the swollen veins of BCTV-infected plants (Fig. 1(F)), in which there are high concentrations of virions. It is not known if beet leafhoppers are preferentially attracted to plants with curly top symptoms, as has been reported for whiteflies (*Bemisia tabaci* species complex) and *Tomato yellow leaf curl virus* (TYLCV).

The pathway BCTV follows in the beet leafhopper was investigated with a PCR-based approach. BCTV-Wor [US-Mld-Wor4] was detected in the digestive tract of the insect after an acquisition access period (AAP) of 1 h, in the hemolymph after 3 h, and in the salivary glands after 4 h, from where it is reintroduced into plants with saliva during feeding. This is consistent with earlier reports estimating the minimum time between virus acquisition and the leafhopper becoming viruliferous (the latent period) to be 4 h. The feeding time necessary for transmission of the virus can be as short as 1 min, though longer feeding times (e.g., inoculation access periods of 24–48 h) provide higher rates of infection. Depending on the length of the AAP, leafhoppers can remain viruliferous for life, although the amount of virus retained and the ability of leafhoppers to transmit the virus declines with time when viruliferous leafhoppers are maintained on plants that are not hosts for the virus. This indicates that the virus is not replicating in the leafhopper. There is also no evidence for transovarial transmission of the virus, a common feature of viruses that replicate in their insect vector.

Several lines of evidence demonstrate that the CP is the determinant of leafhopper transmission specificity. First, BCTV-Wor [US-Mld-Wor4] CP mutants that failed to produce virions are not transmitted by *C. tenellus*. Second, a recombinant virus in which the CP coding sequence of the whitefly-transmitted begomovirus *African cassava mosaic virus* was replaced with that of BCTV produced virions that were transmissible by the beet leafhopper when injected into the hemocoel. Finally, the autonomously replicating nanovirus-like DNA-1 component, normally associated with the whitefly-transmitted begomovirus *Ageratum yellow vein virus*, can be maintained in sugar beet plants infected with BCTV, and is transmitted by the beet leafhopper. These results indicated that the ~1.4 kb DNA-1 molecule is encapsidated by the BCTV CP, although the mechanism is not known, i.e., are two ~1.4 kb ssDNAs or a single ~2.8 kb dimeric ssDNA form (a product of rolling circle replication) encapsidated.

The BCTV-beet leafhopper interaction was further investigated by immunofluorescence and immunolocalization, with antisera raised against *E. coli*-expressed BCTV-Wor [US-Mld-Wor4] CP. BCTV was detected in the mid- and hindgut of viruliferous beet leafhoppers, and distinct fluorescent punctate structures, far greater than the size of an individual virion, were observed on or in the gut walls. These may represent large aggregates of virions (possibly inclusion bodies) acquired from the phloem during feeding or some form of cooperative binding of virions during feeding to form aggregates following initial binding of a small number of virions to the gut wall. Immunolocalization studies revealed vesicle-like structures on the inside of the gut wall, possibly involved in endocytosis of BCTV virions. In the salivary glands, BCTV was mostly localized to the primary salivary gland. The BCTV-Wor alanine scanning mutant CP 25–28 formed virions, but was not leafhopper-transmitted. Dissection PCR and immunofluorescence and immunolocalization revealed that this mutant interacted with the gut in a similar fashion to wild-type virus and entered into the hemolymph, but was not detected in the salivary glands. Thus, this may reveal an amino acid motif of the CP that interacts with a receptor on the salivary gland surface. Together, these results suggest that surface features of the BCTV virion interact in a highly specific manner during circulative transmission through the beet leafhopper, possibly involving two receptor-mediated endocytosis events, i.e., during virus acquisition across the gut wall and movement into the salivary glands. An effort is ongoing to sequence the genome of the beet leafhopper with the goal of identifying the receptors involved in the transmission of BCTV and the microbes tomato big bud phytoplasma and citrus stubborn spiroplasma.

Experimental Systems for Infection of Plants by BCTV

BCTV is poorly (at best) transmitted by mechanical inoculation, which reflects the phloem-limited life style of the virus. Infection can be achieved using a fine-gauge needle (pin-pricking) to introduce virions or viral DNA inoculum directly into the phloem, but the efficiency is low. Particle bombardment is an efficient method for infection of the laboratory host *N. benthamiana* with BCTV, but very inefficient for infection of other hosts. The reason for the difference in host susceptibility to particle bombardment inoculation is not known, and BCTV is phloem-limited in *N. benthamiana*. It is possible that phloem cells susceptible to BCTV infection are more accessible in the leaves of the young (two to four leaf stage) *N. benthamiana* plants inoculated by particle bombardment.

In contrast, high rates of BCTV infection in numerous crops (common bean, cucurbits, pepper, sugar beet and tomato) can be achieved via agroinoculation, in which a multimeric infectious clone is inserted in between the T-DNA borders of a binary

plasmid. This plasmid is transformed into a disarmed strain of *Agrobacterium tumefaciens*, and bacterial cells carrying the binary plasmid are inoculated into stems of young plants just beneath the shoot apex by the needle-puncture method. The *A. tumefaciens* cells bind to wounded plant cells, presumably including nucleate progenitor cells of the phloem, and deliver the T-DNA containing the multimeric BCTV DNA into the nucleus. In the nucleus, the genomic BCTV ssDNA is released from the integrated T-DNA (in transformed cells) by the expressed Rep, which recognizes the IR sequences. The viral infection then proceeds as if the leafhopper had delivered virions into the phloem. Agroinoculation has proven to be a rapid and efficient method of inoculation for BCTV and other geminiviruses, and can be used for screening tomatoes and other crops for resistance to BCTV. This eliminates the need to rely on field plots and natural inoculum, the occurrence of which is highly unpredictable. Agroinoculation has limitations, including difficulties in generating agroinoculation systems for some strains (e.g., BCTV-CO), and the recalcitrance of some plants to *Agrobacterium*-mediated transformation, e.g., pepper.

Management of Curly Top Disease Caused by BCTV

Like many vector-borne diseases, management of curly top disease caused by BCTV has been challenging due to multiple factors. These include the sporadic nature of curly top outbreaks, difficulty in predicting 'bad' curly top years, the migratory nature of the vector and difficulty in managing leafhopper populations with insecticides. In years having severe outbreaks, plants are typically infected at an early stage of development, resulting in substantial yield losses. Resistance to curly top disease is not available in commercial varieties of a number of susceptible crops, including pepper and tomato. Therefore, differences in (1) crop production, (2) the biology of curly top disease in different crops, and (3) the availability of resistant varieties means that management approaches for different crops may vary. However, the most effective curly top disease management will be accomplished through an integrated pest management (IPM) approach. Below, some general strategies for curly top disease management and examples of IPM programs for sugar beet and tomato crops are presented.

Resistant Varieties

The planting of resistant varieties is one of the most effective and environmentally friendly management strategies for any disease. Sources of resistance to BCTV were identified in germplasm of common bean, flax, squash and sugar beet. In the case of sugar beet, mass selection of plants from fields with high incidences of curly top disease led to the identification and release of the first curly top resistant sugar beet variety, US1, in 1933. This variety became widely grown in the western USA, despite some horticultural shortcomings. The identification and selection of resistant sugar beet varieties has been facilitated by the use of breeding plots, known as curly top nurseries, in which large numbers of leafhoppers viruliferous for the most prevalent and virulent strains of BCTV are released. As a result of the high selection pressure in these nurseries, combined with the development of commercial hybrids and molecular breeding technologies, curly top resistance in sugar beet has advanced tremendously despite being a complex quantitatively inherited trait. Modern curly top resistant varieties have greater uniformity, higher yield and improved resistance. However, plants of these resistant sugar beet varieties will develop curly top symptoms and may suffer yield losses when infected at an early stage of development (two to four leaf stage). Therefore, these resistant varieties need to be part of an IPM program that addresses the susceptibility of young plants.

Curly top resistance was also found in a range of common bean varieties (e.g., Red Mexican type), and genetic studies identified a single dominant gene (*Bct-1*) associated with curly top resistance. Breeding efforts led to the release of the commercial curly top-resistant varieties Great Northern UI 15 and Red Mexican UI 34. Subsequently, snap bean varieties with curly top resistance were developed and released. These varieties have provided acceptable yields under high curly top pressure. There is a need to develop curly top-resistant varieties for other market classes of common bean. In terms of tomato and pepper, curly top resistance was not found in commercial cultivars. High levels of resistance were found in accessions of some wild species of tomato, including *Solanum chilense*, *S. habrochaites* and *S. peruvianum*. Unfortunately, introgression of this resistance into commercial tomato varieties has been difficult. Agroinoculation screening of tomato breeding lines with different combinations of *Ty* genes, which confer resistance to the begomovirus TYLCV, with BCTV-Svr and BCTV-LH71 revealed gene combinations, e.g., *Ty-1*, *Ty-2*, *Ty-3* and *Ty-5*, that provided high levels of curly top resistance. The tomato breeding Line 20 #12, carrying the *Ty-1*, *Ty-2* and *Ty-3* genes, has moderate resistance to curly top, which involves initial symptom development followed by recovery. This may indicate that TGS is targeting the viral genome for methylation.

Cultural Practices

Because young plants are more susceptible to infection and suffer the greatest yield losses, some degree of protection can be achieved by adjusting planting dates to avoid exposure of young plants to flights of viruliferous leafhoppers. Typically these flights occur in mid- to late-spring. Thus, early or late planting dates may allow for avoidance of peak leafhopper flights when plants are young, but the difficulty in predicting leafhopper flights from year-to-year is a challenge and populations vary considerably depending on weather conditions and the composition of host plants in overwinter areas. Avoiding the establishment of susceptible crops near leafhopper breeding areas is another strategy that can reduce curly top incidence, though this is limited by land

availability and options for planting crops that are not susceptible to curly top disease (e.g., garlic, melons, onions or small grains). Finally, over-seeding of tomatoes can reduce losses due to curly top disease by allowing for uninfected plants to compensate for yield losses due to infected plants, and to possibly make fields less attractive to migrating leafhoppers, which cue in on patches of brown and green.

Management of the Leafhopper Vector With Insecticides

The most common management strategy is to reduce populations of the beet leafhopper vector in order to reduce the incidence and spread of BCITV. This involves spraying contact insecticides such as malathion or dimethoate and delivering systemic insecticides such as neonicotinoids via sprays, soil drenches or drip irrigation. More recently, technologies have been developed for coating seeds with systemic insecticides. Spraying of contact insecticides can be carried out on weeds in leafhopper breeding grounds or directly on crops such as beans, sugar beets and tomatoes. Ideally, sprays are applied based on monitoring for leafhopper populations with sticky cards or sweep nets. In California, it has been shown that high incidences of curly top in tomato (>10%) require high populations of viruliferous leafhoppers in the spring. This information can inform growers if sprays are necessary. The California Department of Food and Agriculture runs the Curly Top Virus Control Program, the only remaining program that sprays breeding grounds of beet leafhoppers. In this grower-funded program, breeding areas in the rangelands of the foothills on the western edge of the Central Valley are surveyed with sweep nets for beet leafhoppers and malathion is applied when thresholds are reached. The efficacy of this program in reducing incidence of curly top disease in crops remains unclear. Parasites and predators of the beet leafhopper are not uncommon, but it has proven difficult to assess their sustainability or impact on leafhopper populations under natural conditions.

Sanitation

It is not possible to eradicate weed reservoirs in the vast areas that comprise the breeding areas for the beet leafhopper in the western USA. However, in the agricultural valleys where curly top disease is a problem, it is important to practice effective weed management in fields and in non-cultivated areas, as well as around canals and other bodies of water, to eliminate preferred hosts for reproduction of beet leafhoppers, such as Russian thistle (*Salsola sp.*). This can reduce beet leafhopper populations in areas near susceptible crops, as well as those that migrate to the foothills in the fall.

IPM for Curly Top Disease

IPM packages for management of curly top in sugar beet (a preferred host of the beet leafhopper on which it feeds and reproduces) and tomato (a non-preferred host that the leafhopper tastes and then moves on) are different. For sugar beet the IPM package frequently includes: (1) planting cultivars with curly top resistance; (2) early planting dates (to allow plants to reach six to eight true leaves before viruliferous leafhoppers arrive in the fields); (3) management of beet leafhopper populations in fields with insecticides based on an IPM approach, e.g., seed treatment with systemic insecticides followed by mid-season application of a contact insecticide; and (4) sanitation of harvested fields and of weeds on a regional basis. Tomato is not a preferred host of the beet leafhopper, and there are no commercially available resistant varieties. Thus, the IPM package may involve (1) modifying planting dates or the location of fields to avoid leafhopper flights and proximity to leafhopper breeding grounds or flight paths; (2) drenching tomato transplants in the greenhouse and at transplanting with a systemic insecticide; (3) management of beet leafhopper populations in fields with insecticides based on an IPM approach; and (4) sanitation of harvested fields and regional weed management.

Glossary

Benyvirus Siglum derived from *Beet necrotic yellow vein virus*.

Rhizomania Root beardedness (root madness): Extensive proliferation of secondary rootlets at the expense of the main tap root.

Classification

Beet necrotic yellow vein virus (BNYVV) is the type species of the genus *Benyvirus*. This genus is the only one in the new family *Benyviridae* which comprises viruses with multipartite genomes encapsidated in rigid rod-shaped particles. The closest known relative is the *Beet soil-borne mosaic virus* (BSBMV). More distant relationships exist with *Burdock mottle virus* (BdMV) and *Rice stripe necrosis virus* (RSNV). Morphologically similar viruses are found in the family *Virgaviridae*. Similarities and dissimilarities between the viruses in the two families have been summarized in the 10th Report of the International Committee on Taxonomy of Viruses (ICTV).

Virion Structure

BNYVV virus particles are non-enveloped and rod shaped (Fig. 1). The particles have a diameter of about 20 nm and the length varies between 65 and 390 nm depending on the encapsidated RNA species. Deviations from the upper and the lower limits may be due to end-to-end aggregation or breakage of particles. The particles have a helical structure with a central canal. The pitch of the helix is estimated to be 2.6 nm. This helix has an axial repeat of four turns, involving 49 protein subunits of the 21 kDa major coat protein (CP). Each coat protein subunit occupies four nucleotides on the RNAs of BNYVV. Immunogold labeling revealed that the 75 kDa read-through minor coat protein (CP-RT) is predominantly localized close to one end of the virus particles. It had been believed that the CP-RT is necessary to initiate the encapsidation process, but recent investigations showed that it is dispensable for particle assembly and successful virus infection at least in the experimental host *Nicotiana benthamiana*.

Genome Organization and Functions of Gene Products

The BNYVV genome consists of four to five positive-sense single-stranded RNAs (+ ssRNAs) (Fig. 2). Each RNA is capped at the 5' end and possesses a 3' poly(A) tail. RNA1 (6.7 kb) contains one open reading frame (ORF) encoding a replicase protein of 237 kDa (P237), which is processed by a papain-like proteinase into one 150 kDa protein with methyltransferase, helicase and protease domains and one 66 kDa protein containing the RNA-dependent RNA polymerase. Localization studies revealed an association of the P237 protein as well as domains of the 150 kDa and 66 kDa replication-associated proteins with the endoplasmic reticulum (ER). The first ORF on RNA2 (4.6 kb) encodes the CP which is terminated by a leaky UAG stop codon allowing the translation of the readthrough protein CP-RT (P75). The C-terminal part of the CP-RT contains a KTER motif at position 553–556 which is essential for transmission by the vector *P. betae*. Several rounds of mechanical transmission can cause deletions within this region leading to a loss

Fig. 2 Organization of the BNYVV genome and expression of BNYVV genes. Self-cleavage of the replicase protein (P237) is indicated by a black arrow. At 5' end, the m⁷Gppp is indicated by a black circle and the poly(A) tail at the 3' end by A(n). The suppressible leaky stop codon UAG is indicated by *. Abbreviations: methyltransferase (MTR); helicase (HEL); protease (PRO); RNA polymerase (POL); coat protein (CP); readthrough domain (RTD); triple gene block (TGB).

of vector transmissibility. It was shown that a mitochondrial targeting sequence within the CP-RT targets modified CP-RT expressing GFP and reporter proteins to the cytoplasmic face of mitochondria. Furthermore, four trans-membrane domains (TM1-TM4) have been identified by bioinformatic analysis, but their function is not clarified yet. The TM helices are apparently tightly packaged with ridge/groove arrangements between the helices and strong electrostatic association. It is supposed that these helices act as anchors to the mitochondrial membrane in plant cells, but might also facilitate the movement of virus particles across the fungal membrane separating the plasmodium from the cytoplasm. The next three ORFs on RNA2 encode the triple gene block (TGB) proteins 1–3 that are translated from subgenomic RNAs and responsible for cell-to-cell movement. TGB1 (P42) is derived from subgenomic RNA2a whereas TGB2 (P13) and TGB3 (P15) are translated from the bicistronic subgenomic RNA2b. P42 possesses an N-terminal nucleic acid-binding activity and helicase motifs at the C-terminus. Electron microscopy revealed that P13 and P15 localize to callose-containing cell wall thickenings which suggests plasmodesmal targeting by these two proteins. It is proposed that P13 and P15 provide a docking site for a P42-viral RNA complex which modifies plasmodesmal size exclusion limit to improve transit of the viral RNA. The last ORF on RNA2 is translated from the subgenomic RNA2c and encodes the viral suppressor of gene silencing (VSR). It is a 14 kDa cysteine-rich protein (P14) which inhibits the production of small-interfering RNAs (siRNAs), especially secondary siRNAs by interfering with RDR6-dependent siRNA generation. A zinc-finger domain (Znf) containing an embedded nucleolar localization sequence (NLS) has been shown to be crucial for silencing-suppression activity and protein stability. The protein accumulates in the nucleolus and in the cytoplasm, but its suppression activity is probably independent of the subcellular localization. Long-distance movement is abolished in viral mutants carrying a defective VSR.

The first two RNAs of BNYVV are sufficient for virus replication, systemic movement, and symptom development in the experimental host *N. benthamiana*, but characteristic disease symptoms in sugar beet are only induced when RNA3 (1.8 kb) is present. Thus, RNA3 carries the pathogenicity factor of BNYVV, encoded by the 25 kDa protein (P25). P25 possesses a nuclear localization signal (NLS) and nuclear export signal (NES) allowing the protein to shuttle between the nucleus and cytoplasm. The importance of this protein for viral pathogenicity is described in the section 'Virus-Host Relationships'. Downstream of P25 is another ORF located encoding for a 6.8 kDa protein called N gene, but its expression could not be detected under natural infection conditions. However, the N gene is translationally activated by the deletion of upstream sequences leading to a truncated RNA. Expression of this RNA induces necrotic lesions in the local lesion host *Tetragonia expansa*. The last ORF on RNA3 encodes a 4.6 kDa protein of unknown function that is presumably expressed from a subgenomic RNA (RNA-3 sub). Its expression has never been confirmed supporting the presumption that the ORF is cryptic. Besides encoding proteins, the RNA3 additionally has a non-coding function that is crucial for systemic movement. A 'core' nucleotide sequence (at nt position 1033–1257) was identified that mediates systemic movement independent of P25 expression in *Beta macrocarpa*. Within this region, a 20 nt long sequence stretch ('coremin') is crucial for systemic movement. In a study to decipher the function of the 'coremin' nucleotide sequence, a non-coding RNA3 (ncRNA3) was identified, which is a cleavage product that accumulates only when the coremin sequence is present. Production of the ncRNA3 appears to depend on XRN1-type, i.e., plant XRN4 exo-ribonucleases. It has been shown that the ncRNA3 acts synergistically to P14 as a weak second VSR and promotes efficient systemic host infection. The 1.4 kb RNA4 encodes a single 31 kDa protein (P31), which is essential for virus transmission by the vector *P. betae*. Some isolates of BNYVV (see section 'Epidemiology') possess an RNA5 (1.3 kb), containing a single ORF which codes for a 26 kDa protein (P26). The presence of this protein induces necrotic lesions in the host *Chenopodium quinoa* when it is expressed either from RNA5 or from an RNA3-derived replicon. The nucleo-cytoplasmic protein displays a strong transcriptional activity. Interestingly, the 20 nt coremin sequence is also present on RNA5 outside the ORF of P26, indicating a non-coding function of RNA5 during virus movement similar to RNA3.

Transmission

BNYVV is transmitted by the soil-borne ubiquitous plasmodiophorid *Polymyxa betae*, which infects sugar beet to complete its life cycle. *P. betae* can survive in the soil as sporosorus (cytosori), which are resting spores with a very thick and strong cell wall providing persistence in soil for many years under unfavorable conditions. When a host plant is present and sufficient soil moisture available, resting spores germinate and primary zoospores are released. Motile zoospores move through free water in the soil and start encysting on root hairs or epidermal cells of roots. Zoospores penetrate host cells and inject their cytoplasm. A multinucleate plasmodium is formed within the host cell and differentiates either into a zoosporangium releasing secondary zoospores (sporangial phase) or into a sporosorus forming resting spores (sporogonic phase). The secondary zoospores penetrate new root cells and induce plasmodium development. It is suggested that *P. betae* transmits BNYVV when zoospore cytoplasm is injected into the host cell. Likewise, the virus is acquired when a plasmodium develops within an infected host cell. Secondary zoospores released from this plasmodium will be viruliferous. Similarly, sporosorus developed within infected cells will likely release viruliferous primary zoospores. Due to the vector biology, BNYVV can be disseminated by soil adhering to agricultural machines, by irrigation or even by wind. All viral proteins of BNYVV were detected in resting spores and zoospores, however, whether BNYVV is able to replicate within its vector remains to be demonstrated.

Epidemiology

The host range of BNYVV is limited to certain members of the plant families *Amaranthaceae*, *Caryophyllaceae*, *Chenopodiaceae*, and *Tetragoniaceae*. The major natural hosts are *Beta vulgaris* (sugar beet) and *B. macrocarpa*, which are infected and systemically invaded

only when RNA1–4 are present. Spinach (*Spinacia oleracea*) was also identified as natural host, but is only of minor importance. The experimental host *N. benthamiana* is systemically infected in the absence of RNA3 and RNA4. Local lesion hosts for virus propagation are *C. quinoa* and *T. expansa*. Infection is restricted to small chlorotic or necrotic spots without systemic movement after mechanical inoculation. BNYVV was first described in 1950 in Italy and then spread rapidly into sugar beet growing areas worldwide. Restriction fragment length polymorphism, single-strand conformation polymorphism and phylogenetic analysis allowed the identification of four major virus types, namely the A-, B-, P-, and J-type. These different types are serologically indistinguishable, but their RNAs show sequence variability ranging between 1%–5%. The virus types are geographically differently distributed. The A-type is most prevalent with many reports in Europe, USA, and Asia. The B-type has been reported in Germany, France, and other central European countries. The P-type was first described in France in the area of Pithiviers (Center-Val de Loire) and was later discovered also in the UK, Kazakhstan, and a small area in Germany. A great diversity of BNYVV types can be found especially in the Pithiviers area. Within this region, the A-, B-, and P-type are present and occur frequently in mixed infections. Moreover, P-type RNA5 was found in plants infected only with A- or B-type RNAs 1–4 indicating the formation of reassortants. Although RNA5 increases viral aggressiveness, P-type isolates without RNA5 have been reported, indicating its dispensability for viral pathogenicity. The J-type was identified in Asia and has been distinguished from the P-type by sequence analysis. The evolutionary history of BNYVV has not yet been completely resolved, but several subpopulations are thought to have diverged from at least four original types of populations that developed in native hosts in East Asia long before sugar beet was cultivated. Afterwards, BNYVV populations from different origins were introduced into sugar beet cultivation areas and spread extensively. Sequence analysis indicates that the A- and P-type are more closely related than the A- and B-type. Therefore, it is suggested that the A- and B-type became separated before the P-type evolved from the A-type.

Disease Symptoms

BNYVV causes rhizomania. The term signifies root madness (Rhizo: root; Mania: madness). The disease is characterized by excessive lateral root formation ('root beardedness') (Fig. 3). Infected sugar beet plants can display also to some extent dwarfism with a taproot which is reduced in size, has a wine-glass like shape and low sugar content. A brownish discoloration of the vascular

Fig. 3 Characteristic rhizomania disease symptoms on taproot (A) and leaf (B) from a BNYVV infected sugar beet plant compared to a healthy plant (C and D). The white bar indicates the scale (5 cm).

system is often seen. Leaves may become pale and have an upright position. Although symptoms are mostly confined to the root system, infected plants can display vein yellowing and necrosis on leaves after systemic movement of BNYVV to upper plant parts. The name BNYVV refers to these symptoms. Yield losses associated with disease occurrence can range between 50%–60% and are mainly due to reduced root weight and sugar content.

Virus–host Relationships

The pathogenicity of BNYVV is strongly linked to the activity of P25. The protein possesses a nucleo-cytoplasmic shuttling activity allowing the virus to manipulate many cellular processes. Upon BNYVV infection, plants display massive lateral root proliferation leading to the characteristic symptom of a “root beard” only in the presence of P25. Auxin as the major plant hormone controls an array of developmental processes including the development of lateral roots. Microscopic studies of sugar beet roots revealed that differentiated pericycle cells are converted into meristematic cells during BNYVV infection. Additionally, infected plants show elevated auxin concentration in the roots substantiating the hypothesis that BNYVV interacts with the auxin signaling pathway to induce lateral root proliferation. Transgenic *Arabidopsis thaliana* plants expressing P25 displayed also excessive lateral root formation and elevated auxin concentration, which strongly supports the role of P25 in viral pathogenicity. Recent investigations identified an auxin/indole-3-acetic acid (Aux/IAA) transcription factor in sugar beet that interacts with the pathogenicity factor P25 of BNYVV. Aux/IAA proteins are key regulators of the auxin signaling pathway in plants. They act as transcriptional repressors by suppressing the activity of auxin response factors (ARF). ARFs are transcription factors that regulate the expression of auxin-modulated genes responsible for lateral root formation. At low auxin concentration, the transcriptional activity of ARFs is suppressed by Aux/IAA proteins, whereas high auxin concentration promotes the degradation of Aux/IAA proteins, hence releasing ARFs. Aux/IAA proteins are nucleus-localized, whereas P25 shuttles between the nucleus and the cytoplasm. It has been shown that the nuclear localization of a specific Aux/IAA protein (AUX28) is disrupted by P25 leading to an accumulation of AUX28 within the cytoplasm. It is suggested that this interaction leads to the activation of auxin-modulated genes responsible for lateral root development. This hypothesis is further supported by the observation that the expression of genes downstream of Aux/IAA proteins involved in lateral root development are highly induced upon BNYVV infection. P25 is also responsible for the development of symptoms on leaves including vein yellowing and necrosis. Furthermore, P25 interacts with an F-box family protein that is part of the Skp1-Cullin-F-box (SCF) complex and mediates protein degradation. F-box proteins determine the selectivity of the SCF complex as they recruit target proteins. The exact function of the interaction of P25 with the F-box protein is yet unknown. Interestingly, a transcription activation domain could be mapped within the amino acid residues 103 and 160 of P25. This suggests that P25 can directly activate or suppress gene expression in sugar beet; however, target genes are still to be identified. Apart from its function in virus pathogenicity, P25 is also involved in the defense response of resistant cultivars (see section ‘Prevention’).

Diagnosis

Although BNYVV infection induces very characteristic symptoms, the occurrence of leaf symptoms is rare in the field making visual disease diagnosis very difficult. Therefore, serological and molecular detection tools are required for BNYVV diagnosis. Enzyme-linked immunosorbent assay (ELISA) is a common and reliable method to detect the virus within plant parts most likely to be infected (e.g., lateral roots), but BNYVV types are serologically undistinguishable. PCR techniques such reverse transcription-PCR and real-time PCR are also useful for detection using BNYVV specific primers. In addition, sequencing of (cloned) PCR products or next generation sequencing after RNA/dsRNA/virion extraction allows the differentiation of the different BNYVV types and identification of mutations associated with resistance breaking. Infestation of soil can be detected by means of bait plants which are tested for the presence of BNYVV with the aforementioned methods.

Prevention

Methods for controlling the vector *P. betae* by means of pesticides are currently not available. Although soil fumigation with pesticides can reduce the vector population in the soil, severe environmental damage and high economic costs prohibit an application. Resistance traits against the vector were found in *B. patellaris* and *B. procumbens*, but introduction of these traits into commercial sugar beet varieties failed. Therefore, growing of virus resistant cultivars is the only strategy to control rhizomania disease. In 1983, the Holly Sugar Company identified the first resistance gene effective against BNYVV (‘Holly’ resistance). Resistance is based on a single dominant gene (*Rz1*) located on chromosome III. Upon BNYVV infection, *Rz1* confers partial resistance by reducing virus replication. Infected plants do not show disease symptoms or yield loss but the virus can be still detected in lateral roots in low quantities. Most commercial varieties today contain the *Rz1* gene. Further analysis of wild-beet germplasm allowed the identification of a second resistance gene (*Rz2*) in *B. vulgaris* subsp. *maritima* WB42 originating from Denmark, which encodes a CC-NBS LRR (coiled-coil nucleotide binding site, leucine rich-repeat) resistance protein. The gene is also located on chromosome III, but *Rz2* appears to be based on a different mechanism than *Rz1*. The *Rz2* gene has also been

introduced into commercial varieties in combination with *Rz2*. Further resistance genes (*Rz3-Rz5*) located on chromosome III could be identified, but have not been introduced into commercial varieties yet.

With the introduction of the *Rz1* resistance gene into commercial varieties, the virus population was under a high selection pressure. Thus, reports about the emergence of resistance breaking strains in Europe and the USA appeared soon after the introduction of *Rz1*. Such strains can replicate to a higher level and induce disease symptoms in *Rz1* resistant plants, but the resistance breaking mutations are probably associated with a certain fitness loss in susceptible cultivars. Extensive sequence analysis of viral isolates revealed high sequence variability within a stretch of four amino acids (AS67–70) in the pathogenicity factor P25. Mutation analysis with infectious cDNA clones of RNA3 showed that a specific single amino acid substitution on position 67 already mediates *Rz1* resistance breaking. However, the resistance breaking ability for most of the reported sequence variants at AS67–70 is unknown and needs to be determined. Moreover, besides AS67–70, further mutations in P25 are presumably involved in resistance breaking. Interestingly, resistance breaking has so far been reported only for the BNYVV A- and P-type but not for the B-type. The P-type displays a low variability of AS67–70, but is still able to overcome the *Rz1* resistance. BNYVV P-type contains an additional RNA5 encoding the pathogenicity factor P26. It is believed that resistance breaking is mediated by RNA5 rather than by mutations in P25 at AS67–70. Hence, BNYVV has probably developed different strategies to overcome *Rz1* resistance.

Glossary

Benyvirus Siglum derived from beet necrotic yellow vein virus.

Rhizomania Root beardedness (root madness). Extensive proliferation of often necrotizing secondary rootlets at the expense of the main tap root.

History

Beet necrotic yellow vein virus (BNYVV) is the type species of the genus *Benyvirus*. Originally, it was classified as a possible member of the tobamovirus group, because its rod-shaped particles resemble those of tobamoviruses. In 1991, the rod-shaped viruses with multipartite genomes transmitted by species of the plasmodiophorid *Polymyxa* were separated from the monopartite tobamoviruses to form a new group, named furovirus (for 'fungus-transmitted rod shaped viruses'). *Soil-borne wheat mosaic virus* (SBWMV) became the type species of this new group; BNYVV and *Rice stripe necrosis virus* (RSNV) were listed as possible members. Molecular studies conducted in the following years revealed that the genome organization of the members belonging to this new virus group greatly differed from each other. Thus, eventually, four new genera were created, i.e., the genus *Furovirus* with SBWMV as type species, the genus *Benyvirus* with BNYVV as type species, the genus *Pomovirus* with *Potato mop top virus* as type species, and the genus *Pecluvirus* with *Peanut clump virus* as type species. The genus *Benyvirus* presently comprises four definitive species, i.e., BNYVV, *Beet soil-borne mosaic virus* (BSBMV), RSNV and *Burdock mottle virus* (BdMV), and two putative members: *Magnifera indica latent virus* (MILV) and *wheat stripe mosaic virus* (WhSMV). Moreover, a number of beny-like viruses were identified by high throughput sequencing in libraries prepared from several non-plant organisms: a study on invertebrate RNA virus diversity identified a benyvirus-like replication polyprotein gene, the source of this sequence was named *Hubei beny-like virus 1*. Similarly, sequences resembling those in benyviral replicase genes were found in *sclerotium rolfii* and *rhizoctonia solani* in studies aimed at identifying mycoviruses.

Virion Structure, Particle Properties and Associations of Viral Particles With Cellular Structures

Benyviruses are non-enveloped, rod-shaped viruses with multipartite (bi- to pentapartite) positive-single strand RNA (ssRNA) genomes. The RNAs are encapsidated with a coat protein (CP), and in the case of BNYVV also contain the CP-read-through (CP-RT) protein as minor CP in the capsid shell.

The diameter of benyvirus particles is approximately 20 nm. The rods have a central canal and usually show several length maxima ranging from approximately 80 to 400 nm depending on the RNA species encapsidated (Fig. 1). Additional length maxima may be due to end-to-end aggregation or breakage of particles. The right-handed helix of BNYVV particles has a 2.6 nm pitch with an axial repeat of four turns involving 49 subunits of the 21 kDa major CP, which consists of 188 aa. Each CP subunit

occupies four nucleotides on the BNYVV RNAs. The 75 kDa CP-RT protein has been detected by immunogold-labeling on one end of the particles in freshly extracted plant sap. Green fluorescent protein (GFP)-labeled particles of BNYVV localize to the cytoplasmic face of mitochondria early during infection, but later they relocate to semi-ordered clusters in the cytoplasm. In ultrathin sections, BNYVV particles are found scattered throughout the cytoplasm or occur in aggregates. Masses of particles with different densities arranged in parallel or angle-layer arrays may be formed.

Organization of the Genome and Properties of the Encoded Proteins

The functions of the BNYVV proteins and RNAs have been studied in detail. Hence, most knowledge on the genome organization of benyviruses is based on BNYVV; however, aa sequence homologies indicate functional similarities between benyvirus proteins.

The BNYVV genome consists of four to five positive-sense, ssRNAs, while the other benyviruses contain only two to four genomic RNAs (Fig. 2 and Table 1). Four genomic RNA segments have been identified for BSBMV, but only two for BdmV, RSNV, WhSMV and MILV. Each benyvirus RNA is capped at the 5' end and polyadenylated at the 3' end. On RNA1, all benyviruses possess one large ORF encoding the replicase. On RNA2, BNYVV, BSBMV, RSMV, BdmV, and WhSMV all contain six ORFs, of which the first two encode CP and CP-RT proteins, and the following three encode triple gene block (TGB)1, TGB2 and TGB3 movement proteins. The cysteine-rich proteins encoded by the 3' terminal ORF may encode the viral silencing suppressors (VSR), as a VSR function has been shown for BNYVV, BSBMV and BdmV cysteine-rich proteins. An RNA3 and RNA4 has only been identified for BNYVV and BSBMV, but some BNYVV isolates have an additional RNA5. RNA3 of BNYVV and BSBMV, RNA4 of BSBMV and RNA5 of BNYVV contain the 'coremin' sequence, which has been assigned RNA silencing suppressor activity and a function in virus systemic movement. RNA3-encoded BNYVV P25 and BSBMV P29 are the viral pathogenicity factors responsible for symptom development in their major host sugar beet; however, BSBMV RNA3-encoded P29 more resembles BNYVV RNA5-encoded P26 in sequence and function, as it resembles BNYVV P25. The 31 kDa and 32 kDa P31 and P32, encoded on RNA4 of BNYVV and BSBMV, respectively, are involved in vector transmission and symptom development. Moreover, BNYVV P31 has been shown to enhance silencing suppressor activity in roots of *Nicotiana benthamiana*.

The BNYVV large open reading frame (ORF) for the replicase protein encoded on RNA1 is cleaved autocatalytically by a papain-like proteinase. Virus replication may take place in association with the endoplasmic reticulum (ER), as the replication-associated proteins localize to this organelle. In *in vitro* systems, translation of the replication protein may start either at the first AUG at position 154 or at a downstream AUG at position 496–498. The resulting proteins of 237 and 220 kDa, respectively, contain in their N-terminal part methyl-transferase motifs, in their central part helicase and papain-like protease motifs, and in their C-terminal part RNA dependent RNA polymerase (RdRp) motifs.

BNYVV RNA2 contains six ORFs, *i.e.*, the CP gene, which is terminated by a suppressible UAG stop codon, the CP-RT protein gene, a TGB coding for proteins of 42, 13, and 15 kDa, and a gene coding for a 14 kDa cysteine-rich protein. The CP is the major capsid protein important for efficient encapsidation of the virus. Within the 75 kDa CP-RT protein, specific domains appear to be important for virion assembly and vector transmission. A KTER motif at aa position 553–556 of the 75 kDa CP-RT protein is essential for efficient transmission of the virus by *P. betae*. Upon repeated mechanical inoculation of the virus, deletions within the C-terminal part of CP-RT occur and the area containing this motif may be lost, which results in abolished vector transmissibility of the virus. Apart from the KTER motif, trans-membrane domains have been predicted in the CP-RT protein, which presumably aid

Fig. 2 Benyvirus genome structure. Benyviruses contain two to five genomic RNAs with a 5' guanosylmethionine cap (black circle) and a 3' poly A tail (A_n). Benyviruses share the genome structure of RNA1 and RNA2 and encode similar proteins on corresponding open reading frames (ORF). RNAs 3 and 4 encode proteins with partially overlapping functions. RNA5 is only present in BNYVV. RNA1: self-cleavage of the replicase polyprotein between protease (Pro) and RNA-dependent RNA polymerase (RDRP) domains is indicated by a black arrow. Met, methyltransferase domain; Hel, helicase domain. RNA2: Broken line between ORF1 and ORF2 indicates a read-through stop codon. CP, coat protein; CP-RT, CP-readthrough protein; TGB, triple gene block; VSR, viral silencing suppressor. Arrows indicate protein synthesis from coding sequences, broken arrows and question marks indicate that the proteins corresponding to the respective ORFs have not yet been detected.

^cProteins have never been detected in natural infection conditions.

association with distinct vector and host membranes during the viral life cycle. Three sub-genomic RNAs are derived from BNYVV RNA2. The first TGB protein (P42) is translated from sub-genomic RNA2a, the second and third TGB proteins (P13 and P15) from the bicistronic sub-genomic RNA2b, and the 14 kDa cysteine-rich protein from subgenomic RNA2c (Fig. 2). The three TGB proteins are necessary for cell-to-cell movement of the virus. The N-terminal part of the 42 kDa TGB1 protein has nucleic acid-binding activity; its C-terminal part contains helicase motifs. GFP-tagged P42 is targeted by P15 and P13 to punctuate structures associated with plasmodesmata (PD). It has been speculated that P15 and P13 provide docking sites for a P42–viral RNA complex at PD. P42 may alter the PD size exclusion limit to allow virus movement between cells. The 3′ proximal ORF encodes a cysteine-rich 14 kDa protein acting as an RNA silencing suppressor. P14 inhibits secondary siRNA production by interfering with RDR6-dependent siRNA synthesis.

BNYVV RNA3 encodes the 25 kDa P25 pathogenicity factor, which determines symptom severity, likely through reprogramming of auxin signaling within the host plant. In the major host sugar beet, P25 induces massive lateral root proliferation and vein yellowing in systemically infected leaves. The appearance of bright yellow local lesions can be observed on *Tetragonia expansa*. Symptoms seem to depend on the ability of P25 to nucleocytoplasmic shuttling, as mutants unable to shuttle between the nucleus and the cytoplasm fail to induce yellow lesions on *C. quinoa*. The following ORF on RNA 3 encodes a 6.8 kDa N gene, which is not expressed to detectable levels under natural infection conditions. However, expression of the protein is activated by the deletion of upstream sequences, which positions it closer to the 5′ end of RNA3. Expression of the N gene induces the formation of necrotic lesions in BNYVV infections and also when it is expressed from *Cauliflower mosaic virus*. The third ORF on BNYVV RNA3 encodes a protein of 4.6 kDa, which is presumably expressed from an abundantly present sub-genomic RNA; however, a function of this protein is not yet known. RNA3 also contains a functional non-coding RNA (ncRNA), which mediates systemic movement of the virus and functions complementary to P14 as VSR. The RNA3 20 nt ‘coremin’ sequence is responsible for accumulation of the non-coding RNA, as it stalls exoribonucleases of the yeast XRN1 or plant XRN4-type and inhibits RNA processing by the enzymes.

The BNYVV RNA4-encoded 31 kDa P31 protein increases the transmission rate of the virus by *P. betae* and increases symptom severity in *N. benthamiana* and in some Beta species. Moreover, experimental evidence suggests that P31 is able to suppress RNA silencing in roots.

BNYVV RNA5 only occurs in some BNYVV types (P-type and J-type, see section disease, host range and epidemiology below). It enhances symptom expression in sugar beet. Addition of P-type RNA5 to RNA1 and RNA2 results in the formation of necrotic local lesions in *C. quinoa*. P26, the only protein expressed by RNA5, exhibits a nucleo-cytoplasmic localization similar to RNA3-encoded P25 and has been proposed to act synergistically with P25 in symptom development. As RNA5 also contains the 20 nt ‘coremin’ motif it may, in analogy to RNA3, be involved in the systemic movement of the virus.

Blast searches of reference aa sequences of the different benyviruses revealed that the highest sequence similarity between the different members of the benyvirus family is found at the level of the replicase; BNYVV and BSBMV replicase proteins share 85% nt sequence identity. BdMV, RSNV, MILV, and WhSMV replicase proteins share 51%, 44%, 39%, and 31% aa sequence identity, respectively, with the BNYVV replicase protein. Also, the TGB proteins are relatively well conserved with 75%, 82%, and 66% nt identity between TGB1, TGB2 and TGB3 proteins, respectively, of BNYVV and BSBMV; 48%, 49%, and 38% nt identity between TGB1, TGB2, and TGB3 proteins, respectively, of BNYVV and BdMV, and 38%, 44%, and 30% nt sequence identity between TGB1, TGB2, and TGB3 proteins, respectively, of BNYVV and RSNV. The TGB1 and TGB2 proteins of BNYVV and WhSMV share 29% and 45% nt sequence identity, while no significant similarity is found between the TGB3 proteins of the two viruses. The TGB1 and TGB2 proteins of MILV show 27% and 39% nt sequence identity, respectively, with those of BNYVV. At the level of the CP, BNYVV and BSBMV share 59% nt sequence identity, while the CP of BdMV, RSNV, MILV, and WhSMV have 39%, 35%, 27%, and 26% nt sequence identity with BNYVV CP, respectively. The cysteine-rich proteins share only little sequence identity; here BNYVV and BSBMV have 43% aa sequence identity, BNYVV and RSMV 30% and BNYVV and BdMV 22% sequence identity.

Reassortment experiments showed that BNYVV and BSBMV RNA1 and RNA2 reassortants are viable and spread systemically in *N. benthamiana*. The small genomic RNAs 3 and 4 were also exchangeable and systemically infected *B. macrocarpa* and allowed vector transmission. Moreover, rhizomania-specific taproot symptoms in sugar beet could be induced by BSBMV in the presence of BNYVV RNA3 whereas BSBMV RNA3 in combination with BNYVV RNA1 and RNA2 failed to induce taproot symptoms. This underlines the close relationship between both viruses as well as the importance of RNA3 for viral pathogenicity.

Disease, Host Range, and Epidemiology

BNYVV is the causal agent of rhizomania, one of the most damaging diseases of sugar beet. Natural hosts of the virus are *B. vulgaris* ssp. and *B. macrocarpa*. Infections of sugar beet with BNYVV are mainly confined to the root system. Susceptible sugar beet varieties show an extensive proliferation of nonfunctional, necrotizing secondary rootlets, a condition described by the names ‘root beardedness’, ‘root madness’, or rhizomania (Fig. 3). The taproots are stunted, their shape tends to be constricted, and their sugar content is low. A brownish discoloration of the vascular system is often seen. Leaves may become pale and have an upright position. Under dry conditions, wilting is often observed due to insufficient water uptake by the roots. The upper parts of the plants are invaded only rarely by the virus. In infected leaves, the veins turn yellow, and occasionally become necrotic, a condition after which the virus was named (Fig. 3). In susceptible varieties, rhizomania may cause yield losses of 50% and more. Like other diseases caused by soil-borne organisms, rhizomania often occurs in patches within infected fields. BNYVV can be mechanically

Fig. 3 Benyvirus symptoms on sugar beet. Typical symptoms on roots and leaves of BNYVV (A) and BSBMV (B) infected sugar beet. Plants were mechanically inoculated with the virus (C) shows a root and a leaf of a healthy control plant.

transmitted to many species in the *Chenopodiaceae* and to some species in the *Amaranthaceae* and *Tetragoniaceae* as well as to *N. benthamiana*. *B. macrocarpa*, *S. oleracea* and *N. benthamiana* become infected systemically. BNYVV occurs in sugar beet-growing areas worldwide. Molecular analyses have revealed the existence of different BNYVV types (A type, B type, P type, and J-type) that cannot be distinguished serologically. The A type is most common and occurs in Europe, in the USA, and in East Asia. The B type is prevalent in Germany, France, and other central European countries. B-type-like BNYVV is also found in East Asian countries. The P type, which usually contains an RNA5 and causes especially severe symptoms, has only been found in restricted areas in central France (Pithiviers), the UK, Germany and in Kazakhstan. The J-type has been identified in Asia. The current BNYVV types seem to have evolved from at least four original populations that developed in native hosts in East Asia and spread from there. Naturally infected local hosts in different geographic regions may harbor various types of BNYVV. Once transmission from a native host to sugar beet has been successful, further spread in beet-growing areas by machinery, irrigation, or infested soil may be very rapid.

The symptoms caused by BSBMV on its natural host *B. vulgaris* are more variable than those produced by BNYVV. Infected roots may remain symptomless (Fig. 3) or occasionally show rhizomania-like symptoms. Infections of the upper parts of the plants occur more frequently than with BNYVV. Leaves may develop vein banding or faint mottling. When plants are dually infected with BSBMV and BNYVV, foliar symptoms appear more frequently. In general, BSBMV causes much less damage to sugar beet than BNYVV. It has been reported that, when present in mixed infections, BNYVV suppresses BSBMV. In addition, at the cellular level, BNYVV and BSBMV remain spatially separated. BSBMV can be transmitted mechanically to *C. quinoa*, *Chenopodium album*, and *T. tetragonioides*, all of which become infected locally, and to *Beta maritima*, which becomes infected systemically. BSBMV is widely distributed in the USA, but has so far not been found in other parts of the world. Analyses of polymerase chain reaction (PCR) products indicated that this virus is genetically much more variable than BNYVV. This may explain the variability in the symptoms produced by this virus.

RSNV was identified in 1983 in West Africa (Ivory Coast) as the causal agent of a long-known disease named 'rice crinkling disease'. The percentage of infection varies greatly between varieties and in different years. RSNV also occurs in additional African countries, so in Liberia, Nigeria, and Sierra Leone. Recently, RSNV was identified in Burkina Faso (2014), Benin (2015), and Mali (2017). In South America, the virus was first noticed in Columbia, where it causes a severe disease of rice named 'entorchamiento' that is characterized by seedling death, foliar striping, and severe plant malformation and is also present in Ecuador, Brazil and Panama. Recently, (2018) RSNV was also reported in Argentina. The virus can be transmitted mechanically to *C. quinoa*, *C. album*, and *Chenopodium amaranticolor* where it produces local lesions, but not to rice. *N. benthamiana* does not become infected.

BdMV has been isolated from leaves of naturally infected burdock (*Arctium lappa* L.) plants in Japan in 1970. Leaves as well as roots of this plant are common vegetables in Japan. BdMV causes mild chlorosis or mottling symptoms on leaves of burdock plants, the only known natural host of the virus. The symptoms can become masked in older plants. BdMV can be transmitted mechanically to *C. quinoa*, *C. murale*, *N. clevelandii*, and *N. rustica*, which are infected systemically, and to *B. vulgaris* var. *cicla* and var. *rapa*, *S. oleracea*, *Cucumis sativus*, and *T. expansa*, which are infected only locally, some of them only with difficulty. So far, BdMV has only been reported to occur in Japan.

WhSMV has only recently (2019) been isolated from wheat plants in Brazil showing chlorotic to necrotic stripes on the leaves, symptoms of soil-borne wheat mosaic disease typically associated with SBWMV and wheat spindle streak mosaic virus, and causes strong crop losses in Brazil.

Transmission

BNYVV, BSBMV and presumably also RSNV and WhSMV are transmitted by species of the obligate biotrophic root parasite *Polymyxa*. While direct evidence for the transmission of BNYVV and BSBMV by *Polymyxa betae* exists through transmission studies, the evidence, that RSNV and WhSMV are transmitted by *P. graminis* remains correlative, based on the consistent occurrence of the pathogen in virus infected roots. Whether the other members of the benyvirus family are also transmitted by plasmodiophorids is not yet known. RSNV-harboring cystosori may be carried in soil adhering to the surface of rice seeds, but true seed transmission has not been observed. Under experimental conditions, benyviruses are readily transmitted mechanically among test plants. However, attempts to transmit BNYVV mechanically from sugar beet rootlets to test plants may not always be successful.

The *Polymyxa* life cycle begins with the encystment of a zoospore on a host plant root epidermal or root hair cell, injection of the spore content into the host cytoplasm and the formation of a plasmodium inside the host cell. It is believed that virus transmission to the host and acquisition of virus from the host takes place during this plasmodial phase. The plasmodium then differentiates either into a zoosporangium or into resting spores; the mechanisms driving entry into a zoosporangial or sporogenic phase are not yet understood. BNYVV virus-like particles were found inside *P. betae* zoosporangia and proteins associated with viral replication and movement have been detected inside *P. betae* zoospores and resting spores, allowing the hypothesis that virus replication and movement may take place within *Polymyxa*. Whether *Polymyxa* may indeed be a host for the virus remains to be shown. Virus present in *Polymyxa* resting spores remains infective for many years. The spores may be distributed on agricultural equipment, by irrigation, or even by wind.

Diagnosis

The presence of symptoms typical for BNYVV is a good first indicator for benyvirus infection. Root symptoms, *i.e.*, rootlet proliferation and necrosis of vascular bundles are considered reliable indicators of infection. However, symptoms on the foliage of plants in the field can easily be confused with those resulting from other causes, *e.g.*, infection with other viruses, nematodes, fungi, or abiotic stress such as nitrogen deficiency. Thus, benyvirus infections are diagnosed most reliably by serological or molecular biological techniques, bioassays with indicator plants, electron microscopy or a combination of these techniques. Benyviruses are moderately to strongly immunogenic. Polyclonal antibodies have been obtained for BNYVV, BSBMV, and RSNV. BNYVV and BSBMV are only very distantly serologically related – some antisera may detect only one of the two viruses. Particles of RSNV and BdMV do not react with antisera raised against BNYVV. Monoclonal antibodies against BNYVV have been used for diagnostic purposes and for determining the accessibility of aa on the virus particles. Single-chain antibody fragments have also been produced and used to detect BNYVV. Enzyme-linked immunosorbent assay (ELISA), immunoelectron microscopy, tissue-print immunoblotting, western blot, and immunocapture PCR are serological methods commonly used for the detection of benyviruses. Molecular biology techniques based on RT-PCR or sequencing are also routinely applied for the diagnosis of benyviruses. Especially the identification of the putative new benyvirus member species has been achieved by next generation sequencing (NGS) technology. An advantage of PCR-based methods alone or in combination with sequencing of PCR products as well as of NGS is that they allow the discrimination of different virus types or strains, which are serologically indistinguishable and, in the case of NGS, allow the identification of viruses without the requirement of *a priori* sequence information. Electron microscopy techniques, *i.e.*, transmission electron microscopy, immunoelectron microscopy, or immunogold labeling are also possibilities to diagnose benyvirus infection. Bioassays relying on mechanical inoculation of indicator plants are also useful, though laborious. Infestation of soil may be detected by means of bait plants, which are planted into contaminated soil and tested for the presence of virus, usually by ELISA or with PCR-based methods.

Control

Polymyxa-transmitted plant viruses may survive in soil in the long-living resting spores of the vector for many years, probably even decades. The diseases caused by these viruses are therefore difficult to control. Chemical approaches, e.g., by soil treatment with methyl bromide, is neither efficient nor acceptable for economic and ecological reasons. Growing resistant or tolerant varieties currently represents the only practical and environmentally friendly means to lower the impact of these diseases on yield. BNYVV-tolerant or partially resistant sugar beet varieties are available which enable good yields also on infested fields. Their resistance is based mainly on the Rz1 gene from a sugar beet line ('Holly' resistance) and the Rz2 gene from the *B. maritima* line WB42. Rz1 resistance-breaking BNYVV strains have been reported, but presumably lose their advantage in susceptible varieties. The resistance breaking properties have been associated with aa in the P25 pathogenicity factor as well as with the presence of RNA5. Additional resistance genes (Rz3 to Rz5) have been identified, but have not yet been introduced into commercial varieties. Among the different known loci conferring resistance to BNYVV, all located on Chromosome III in *B. vulgaris*, only Rz2 has been identified to encode a CC-NBS-LRR (coiled-coil, nt binding site, leucine rich-repeat) resistance protein. These proteins typically act to restrict virus infection during effector-triggered immunity. Genetically modified sugar beet expressing various portions of the BNYVV genome have been shown to be highly resistant to BNYVV. Resistance against the vector has been detected in *B. patellaris* and *B. procumbens*, but attempts to develop agronomically acceptable sugar beet cultivars resistant to *P. betae* have so far failed.

The degree of resistance or tolerance to RSNV differs in different rice cultivars. A high degree of resistance is found in *Oryza glaberrima*. Studies with *O. glaberrima* x *O. sativa* introgression lines allowed the identification of an RSNV resistance locus on chromosome 11. This resistance locus has so far not been introduced into commercial varieties.

Apart from growing resistant plants, prevention methods consisting of stringent hygiene and decontamination procedures for contaminated material and instruments may help to limit further spread of the pathogen.

Similarities and Dissimilarities With Other Taxa

The morphology of benyviruses resembles that of other rod-shaped viruses, that is, of furoviruses, goraviruses, hordeiviruses, pecluviruses, pomoviruses, tobamoviruses and tobnaviruses. Phylogenetic relationships between benyviruses and viruses from other genera and similarities with other taxa have been extensively reviewed in the 10th report of the International Committee on Taxonomy of Viruses. The benyvirus genomes are multipartite with two to five RNAs. Tobamoviruses have monopartite, goraviruses, furoviruses, pecluviruses, and tobnaviruses bipartite, and hordeiviruses and pomoviruses tripartite genomes. The fact that the RNAs of benyviruses are polyadenylated differentiates them from the RNAs of the other viruses listed above. Opposed to the other rod-shaped viruses, which encode their replication-associated proteins in two ORFs, benyviruses have a single large ORF on their RNA1 coding for a polypeptide, which is cleaved post-translationally into two replication-associated proteins. The replication-associated ORFs of hordeiviruses are located on two different RNAs; in the case of furoviruses, gora-, peclu-tobamo-, and tobnaviruses, the ORFs coding for replication proteins are located on the same RNA, where ORF1 is terminated by a leaky stop codon and extends into an ORF2. The methyl-transferase, helicase, and RNA-dependent RNA polymerase motifs in the benyvirus replicase display higher similarity to e.g., *Hepatitis virus E* and *Rubella virus* than to other rod-shaped plant viruses, and database similarity searches of benyviral replicase sequences reveal similarities to sequences in plant-, fungal- and invertebrate-derived NGS sequencing libraries. Taken together, this supports a model in which benyviruses may have specialized from ancestors infecting a wide range of hosts.

Like hordei-, gora-, peclu-, and pomoviruses, benyviruses have their movement function encoded on a TGB. Sequence comparisons reveal similarities within the first and second TGB-encoded proteins of hordei- and pomoviruses as well as to carla- and potexviruses.

With respect to structural motifs in RNA, it is interesting to note that the 'coremin' motif present on BNYVV and BSBMV RNAs is also present on *Cucumber mosaic virus* RNAs. One of the functions assigned to this motif is stalling of host exonucleases, resulting in the production of ncRNAs with functions associated with virus movement and silencing suppression.

nt Nucleotide(s)

ORF Open reading frame

Pol RNA-dependent RNA polymerase

P-Pro Papain-like protease

Rep Replication initiator protein

S_{20,w} Corrected sedimentation coefficient; extrapolated in water at 20°C and infinitely diluted

sgRNA sub-genomic RNA

ssRNA single-stranded ribonucleic acid

TGB Triple gene block

Glossary

Alfavirus A genus in the family *Togaviridae*. The type species is *Sindbis virus*.

Helical symmetry A form of capsid structure found in many RNA viruses in which the protein subunits which interact with the nucleic acid form a helix.

Movement protein A virus-encoded protein which is essential for the cell-to-cell movement of the virus in plant tissues.

RNA silencing suppressor Viral protein that suppresses the antiviral RNA silencing response by the host.

Semi-persistent transmission The relationship between a plant virus and its arthropod vector which is intermediate between non-persistent transmission and persistent

transmission. It has the features of short acquisition feed and no latent period found in non-persistent manner, but the vector remains able to transmit the virus for periods of hours to days which is longer than the non-persistent manner.

Sub-genomic RNA A segment of RNA generated from a genomic RNA via an internal promoter that has the same 3' end as the genomic RNA, but has a deletion at the 5' end. The sub-genomic RNA makes it possible to efficiently translate the downstream open reading frame of the genomic RNA.

The 30K superfamily The group of movement proteins related to the 30 kDa ('30K') movement protein of Tobacco mosaic virus.

Introduction

Betaflexiviridae is a family of viruses in the order *Tymovirales* and contains viruses infecting plants and sharing a distinct lineage of alphavirus-like replication proteins. The viruses in this family have flexuous particles composed of a single stranded (plus-sense), polyadenylated RNA genome, and a single coat protein. In the ICTV 9th report (2009 release), six genera (*Capillovirus*, *Carlavirus*, *Citriivirus*, *Foveavirus*, *Trichovirus*, and *Vitivirus*) were established in this family. Now in 2019, two subfamilies and six new genera have been added, and the family *Betaflexiviridae* now consists of two subfamilies and 12 genera including 107 species, and 27 tentative species in the family.

Taxonomy and Phylogeny

The members of the family *Betaflexiviridae* are classified in two subfamilies *Quinvirinae* and *Trivirinae* and twelve genera: four genera; *Carlavirus*, *Foveavirus*, *Robigovirus* in the subfamily *Quinvirinae*, and eight genera; *Capillovirus*, *Chordovirus*, *Citriivirus*, *Divavirus*, *Prunovirus*, *Tepovirus*, *Trichovirus*, *Vitivirus*, and *Wamavirus* in *Trivirinae* in the subfamily *Trivirinae* (Table 1). Three species in the subfamily *Quinvirinae*; *Banana mild mosaic virus*, *Banana virus X*, and *Sugarcane striate mosaic-associated virus* are not assigned to any genera yet. The viruses in the subfamily *Quinvirinae* have the 'triple gene block' (TGB) as the proteins involved in cell-to-cell movement. On the other hand, the members in the subfamily *Trivirinae* have a single movement protein (MP) of the 30K superfamily (Table 2). The genus demarcation criteria in this family are less than 45% nt sequence identity and 40% aa identity in the replication-associated protein (Rep) and coat protein (CP), and the different species within the same genus should have less than 72% nt identity (or 80% aa identity) in the Rep and CP genes.

Phylogenetic analysis of the aa sequences of the Rep (POL) and CP of 106 members in the family *Betaflexiviridae* are shown in **Fig. 1(a)** and **(b)**. A phylogenetic tree constructed using POL sequences showed that the two subfamilies are separated and members in most genera are grouped into distinct clusters (**Fig. 1(a)**). As an exception, ASGV, a type species of the genus *Capillovirus*, and another three species (*Cherry virus A*, *Currant virus A*, and *Mume virus A*) are separated into different clusters. In a phylogenetic tree using the CP sequence (**Fig. 1(b)**), members of the genus *Foveavirus* are grouped into two different clusters which were divided into two subfamilies. Phylogenetic trees based on aa sequences of TGB1 proteins for the members of the subfamily *Quinvirinae* and MPs of the members of the subfamily *Trivirinae* are shown **Fig. 1(c)** and **(d)**, respectively. In the subfamily *Quinvirinae* -TGB1, members of the genus *Carlavirus* are divided into several clusters (**Fig. 1(c)**).

Members of the Family

The number of virus species within each genus varies greatly depending on the genus, the largest genus *Carlavirus* contains 53 species and the smallest ones *Citriovirus* and *Wamavirus* consist of only one virus species (**Table 1**). There is another 27 betaflexiviruses that are tentative members for some genera, and for which full sequences are already available (**Table 1**).

Fig. 1 Phylogenetic relationships among virus species in the family *Betaflexiviridae*. Phylogenetic tree was constructed by CLUSTAL W based on the amino acid sequences of the polymerase of viruses in the family *Betaflexiviridae* (1a), the coat protein of viruses in the family *Betaflexiviridae* (1b), the TGB1 protein of viruses in the subfamily *Quinvirinae*, and movement protein (MP) of viruses in the subfamily *Trinvirinae*. The POL amino acid sequences of 106 viruses classified in the family *Betaflexiviridae* (approved and tentative) were collected from Ref-seq database at July 2019. Virus species in each genus were selected from the virus reference sequence collection of the gene bank. The abbreviations of the viruses are listed in Table 1.

Virion Structure

Virions are non-enveloped, flexuous filamentous particles, 610–960 nm long and 10–13 nm in diameter, depending on the genus and species (Table 2). They have helical symmetry with a pitch of about 3.4 nm (range 3.3–3.7 nm). Electron micrographs of members of the genera *Potyvirus* (*Potyviridae*), *Potexvirus*, (*Alphaflexiviridae*), *Closterovirus* (*Closteroviridae*), *Carlavirus*, *Foveavirus*, *Capillovirus*, *Trichovirus*, and *Vitivirus* (the last five are in the family *Betaflexiviridae*) suggests that the flexibility and surface structure of the virus particles are not significantly different between Zucchini yellow mosaic virus (*Potyvirus*), Potato virus X (*Potexvirus*), and three carlaviruses (Potato virus S, Southern potato latent virus, and Strawberry pseudo mild yellow edge virus). On the other hand, the particle flexibility and cross-banding structure of Apple stem pitting virus (ASPV) (*Foveavirus*), Apple stem grooving virus

Fig. 1 Continue.

(ASGV) (*Capillovirus*), Apple chlorotic leaf spot virus (ACLSV) (*Trichovirus*), and Grapevine virus A (*Vitivirus*) resembles to those of Citrus tristeza virus (*Closterovirus*) (Fig. 2).

Virions of the members in the *Betaflexiviridae* sediment as a single species with a sedimentation coefficient ($S_{20,w}$) of 92–176S, depending on the genus and species. Virions are composed of a linear positive-sense, single-stranded RNA (ssRNA) of 5.8–9.3 kb which is 5%–6% by weight of the virion and a single coat protein of Mr of 18–44 kDa (Table 2). The 3' terminus of the genomic RNA has a poly(A)-tail and the 5' terminus has a cap structure.

The particles of ASPV (*Foveavirus*) readily form end-to-end aggregates with four prominent peaks appearing at 800 nm, 1600 nm, 2400 nm, and 3200 nm in length in purified preparation. ACLSV particles require the presence of divalent cations (for example, Mg^{2+}) to maintain the integrity of the quaternary structure. Potato virus T (*Tepovirus*) particles stained with uranyl formate showed cross-banding structure similar to ASGV (*Capillovirus*), whereas those stained with uranyl acetate showed 'criss-cross' and rope structure.

Genome Organization

The number of open reading frames (ORFs) encoded by viral genomes is between two and six depending on the genus (Table 2 and Fig. 3). In all species, the ORF1-encoded product has homologies with polymerase proteins of the 'alphavirus-like' supergroup of RNA viruses. This protein (Rep) (190–250 kDa) contains the conserved domains for methyl-transferase (Met), helicase (Hel), and RNA-dependent RNA polymerase (Pol) activity (Fig. 3). Most members also have a DNA alkylation damage repair protein (AlkB) and/or a papain-like protease (P-pro) domains between the Met and Hel (Fig. 3). Smaller ORFs encode the proteins involved in cell-to-cell movement, either a 'triple gene block' (TGB) (*Carlavirus*, *Foveavirus*, and *Robigovirus*) or a single MP of the '30K' superfamily (*Capillovirus*, *Chordovirus*, *Citrivirus*, *Divavirus*, *Prunevirus*, *Tepovirus*, *Trichovirus*, and *Vitivirus*) (Table 2 and Fig. 3). These are usually located following (3' proximal) the polymerase but in the genomes of capilloviruses and divaviruses, ORF2 (MP) is nested within the ORF1 (Fig. 3). For vitiviruses, an extra ORF with unknown function is present between the polymerase and MP genes. Watermelon virus A (*Wamavirus*) also have an additional protein of unknown function between MP and CP (Fig. 3). The CP

Fig. 2 Electron micrographs of (1) Zucchini yellow mosaic virus (*Potyvirus*), (2) Potato virus X (*Potexvirus*), (3) Potato virus S (*Carlavirus*), (4) Southern potato latent virus (*Carlavirus*), (5) Strawberry pseudo mild yellow edge virus (*Carlavirus*), (6) Citrus tristeza virus (*Closterovirus*), (7) Apple stem pitting virus (*Foveavirus*), (8) Apple chlorotic leaf spot virus (*Trichovirus*), (9) Grapevine virus A (*Vitivirus*), and (10) Apple stem grooving virus (*Capillovirus*). Bars represent 100 nm. (7) Courtesy of H. Koganezawa, (9) Courtesy of J. Imada.

gene always follows a single MP or TGB except a member of the genus *Wamavirus*. There is also another ORF at the 3' terminus in the genera *Carlavirus*, *Prunevirus*, and *Vitivirus* and in some species of *Trichovirus*. This latter ORF encodes a putative RNA-binding protein (NBP) with a zinc binding finger motif and the ability to bind nucleic acids (Fig. 3).

Properties and Functions of Gene Products

All members in the family *Betaflexiviridae* encode functional proteins for replication (Rep), cell-to-cell movement (a single MP or TGB), and protection of the genome RNA (CP). A small RNA binding protein is also encoded in all, or some members, in the genera *Carlavirus*, *Prunevirus*, *Vitivirus*, and *Trichovirus*. As an additional function, an RNA silencing suppressor activity is found in some proteins. For PVM in the genus *Carlavirus*, both a TGP protein 1 and a cysteine-rich 11K protein (ORF6) act as viral suppressor for local and systemic silencing, respectively. An ORF5 protein of Grapevine virus A (GVA) in the genus *Vitivirus* also suppresses local and systemic silencing. On the other hand, MPs of Citrus leaf blotch virus in the genus *Citrivivirus* and ACLSV in the genus *Trichovirus* have activity of silencing suppressors in which the former suppresses both local and systemic silencing, and the latter inhibits only systemic silencing.

Replication and Propagation

Members in the family *Betaflexiviridae* are alleged to replicate in the cytoplasm of infected cells. Virus particles are observed as aggregates in the cytoplasm but not frequently. Viral genomic RNA is infectious and serves as a viral messenger RNA. The ORF1 protein (Rep) is translated directly from the genomic RNA and probably the products are proteolytically processed by a P-Pro in Rep for maturation. The other ORFs located in the 3' terminus of the genome are expressed from sub-genomic mRNAs (sgRNAs). Northern blot hybridization analysis of virus-specific double-stranded (dsRNA) and ssRNAs in ASPV (*Foveavirus*)-infected tissues showed the presence of five distinct dsRNAs (ca. 9 kbp, 7.5 kbp, 6.5 kbp, 2.6 kbp, and 1.6 kbp) and three ssRNA (ca. 9 kb, 2.6 kb, and 1.6 kb) in infected tissues (Fig. 4). The slowest migrating ssRNA (9 kb) was equivalent to that of the ASPV genome,

Fig. 3 Gemome organization of representatives of virus species from the twelve genera in the family *Betaflexiviridae*. GaLV, Garlic latent virus; ASPV, Apple stem pitting virus; CNRMV, Cherry necrotic rusty mottle virus; ASGV, Apple stem grooving virus; CtChV1, Carrot Ch virus 1; CLBV, Citrus leaf blotch virus; DiVA, Diuris virus A; ApVCaV, Apricot vein clearing associated virus; PVT, Potato virus T; ACLSV: Apple chlorotic leaf spot virus; CMLV, Cherry mottle leaf virus; GVA, Grapevine virus A; WVA, Watermelon virus A. Met, methyltransferase; AlkB, a DNA alkylation damage repair protein; P-pro, papain-like protease; Hel, nucleotide triphosphate-binding helicase; Pol, RNA dependent RNA polymerase; CP, coat protein; MP, movement protein; TGB, triple gene block.

Fig. 4 (a) Northern blot analysis of double-stranded RNA (dsRNA) and single-stranded RNA (ssRNA) in leaves of *Nicotiana occidentalis* infected with Apple stem pitting virus (ASPV IF-38) using three different RNA probes specific to different sequences within the genomic RNA. Lane 1: a probe complementary to nt positions 6207 to 6683 (ORF1 region), lane 2; nt positions 6678 to 7447 (ORF2 region), and lane 3; nt positions 8717 to 9293 (CP and the 3' non-coding regions). gRNA, genomic RNA; sgRNA, sub-genomic RNA. (b) The predicted positions of ASPV-specific dsRNAs, genomic RNA (gRNA) for Rep, sub-genomic mRNA1 (sgRNA1) for TGB, and sgRNA2 for CP.

and other two ssRNAs (2.6 kb and 1.6 kb) are thought to be sgRNAs of TGB proteins (ORF2–4) and CP (ORF5), respectively. The dsRNA species with 7.5 kbp and 6.5 kbp, the function of which are unknown, are 5' co-terminal with genomic dsRNA. Similar patterns of dsRNAs and the 3' terminal sgRNAs are reported in infections with members of the genera *Capillovirus*, *Carlavirus*, and *Trichovirus*.

Transmission and Host Range

Most of the viruses in the family *Betaflexiviridae* are transmitted by mechanical inoculation, although the difficulty varies depending on the species. Transmission by grafting and dispersal through propagating materials is common in all species, especially in viruses that occur in woody fruit trees. Most members in the genus *Carlavirus* are transmitted by aphids in the non-persistent manner. Cucumber vein-clearing virus (*Carlavirus*) is transmitted by whiteflies. No vectors of any species have been reported for viruses in the genera *Foveavirus*, *Robigovirus*, *Capillovirus*, *Divavirus*, *Citriovirus*, *Chodovirus*, *Tepovirus*, and *Prunovirus*. However, some trichoviruses, i.e., Cherry mottle leaf virus and Grapevine berry inner necrosis virus are known to be transmitted by the peach bud mite *Eriophyes insidiosus* and the grape mite *Colomerus vitis*, respectively. For vitiviruses, both GVA and Grapevine virus B are transmitted in nature by several species of the pseudococcid mealybug genera *Planococcus* and *Pseudococcus* in a semi-persistent manner, whereas Heracleum latent virus is transmitted from naturally infected hogweed plants by aphids in a semi-persistent manner, which depends on a helper virus present in naturally infected plants. ASGV (*Capillovirus*) has been known to be transmitted through seeds to progeny seedlings of lily (1.8%) and *Chenopodium quinoa* (2.5%–60%). PVT (*Tepovirus*) is readily transmitted through true potato seed and pollen and spreads to tubers produced by infected plants. With the exception of most viruses in the genus *Carlavirus*, many viruses in this family use woody plants (fruit trees) as hosts, for example, rosaceae fruit trees for foveaviruses, robigoviruses, capilloviruses, prunoviruses, tepovirus, and trichoviruses, grapevines for foveaviruses, trichoviruses, and vitiviruses,

and citrus plants for capillovirus and citrivirus. Some viruses cause diseases in fruit trees, but many viruses are infecting fruit trees without showing obvious disease.

Geographical Distribution

Geographical distribution of viruses in the family *Betaflexiviridae* ranges from wide to restricted according the genus and the species. For example, ACLSV, ASGV, and APSV occurs in all countries where apples are grown, in contrast that GINV occurs only in Japan.

Glossary

Betasatellite ssDNA satellite molecules about 1300 nt long and coding for a pathogenicity determinant protein, which depends on a geminivirus helper for replication, movement, encapsidation and transmission.

Deltasatellite Small non-coding ssDNA satellites about 700 nt long, associated with helper begomoviruses.

Iterons High-affinity binding sites located upstream of the stem-loop of geminiviruses.

Pathogenicity determinant protein Any protein coded by virus or the satellite which determines the virulence of the pathogen.

Satellite conserved region A highly conserved region of ~ 80 nucleotides, which is integral part of all the betasatellites.

Satellite DNA Subviral agent consisting of ssDNA that becomes packaged in protein shells made from coat protein of the helper virus and whose replication, movement and transmission is dependent on that virus.

Introduction

Betasatellites are small circular sub-viral components associated with geminiviruses and are mainly confined to the Old World. The word “beta” was used to differentiate with the DNA-B component of begomoviruses and the word “satellite” was added because they are effectively satellites. Their discovery started from the identification of a satellite molecule associated with Tomato leaf curl virus in Australia (now classified under the genus *Deltasatellite* of the family *Tolecusatellitidae*). Betasatellites have very conserved sequence structure or genome organization which includes an adenosine rich (A-rich) region, a satellite conserved region (SCR) and a small open reading frame coding for a protein called β C1. Initially, they were associated with monopartite begomoviruses, but nowadays they are routinely identified in association with bipartite begomoviruses as well. So far, betasatellites have been limited to the Old World, however a recent discovery suggests that a defective form of an African-origin betasatellite (Cotton leaf curl Gezira betasatellite – lacking β C1) has been found in the United States.

The DNA-A component alone of begomoviruses, in many cases, is sufficient to induce the disease symptoms. Nevertheless, for an increasing number of begomoviruses, betasatellites are crucial to induce the typical disease symptoms. For example, Cotton leaf curl Gezira virus in Africa, Cotton leaf curl Multan virus in Pakistan and Tomato yellow leaf curl China virus in China require the presence of a betasatellite for disease development. Betasatellites are trans-replicated and encapsidated by their helper virus Rep protein and coat protein (CP) respectively. In the laboratory conditions Old World betasatellites can replace the functions of a DNA-B component. However, New World begomoviruses can also maintain the betasatellites without compromising the function of the DNA-B component.

The first betasatellite was characterized for the Ageratum yellow vein disease in 2000. The presence of the betasatellite increased viral symptoms in ageratum plants infected with the geminivirus. Subsequently several betasatellites were characterized from Asia and Africa. For several diseases in tomato, tobacco, cotton, chillies, and okra, the helper viruses do not require the absolute presence of a betasatellite for the disease development. To date, more than 1880 sequences of betasatellites are present in GenBank. The betasatellites not only interfere with the normal plant development, but they act as a suppressor of transcriptional and post-transcriptional gene silencing.

Classification and Nomenclature

Betasatellites and deltasatellites are satellite molecules, therefore dependent on a helper virus for their replication and/or other biological functions. Their classification is based on their genomic nucleic acid sequence. Since 2016, the species demarcation threshold for beta- and deltasatellites has been set to 91% nucleotide sequence identity. This species demarcation threshold will be soon revised as it seems

Table 1 List of species of the genera *Betasatellite* and *Deltasatellite* of the family *Tolecusatellitidae*. A list of betasatellite unassigned species is indicated. The acronym and isolate ID of the reference virus for each species, as well as the NCBI GeneBank accession number and the length of the satellite are also provided. Type species for each genus are written in bold

^aUnassigned betasatellite species.

that the distribution of pairwise comparison sequence (PASC) values indicate a clear difference between isolates, species and genera, pointing to a cut-off value closer to 73% for species demarcation. Currently the ICTV recognizes 61 species of betasatellites and 11 species of deltasatellites. In addition, 12 tentative species of betasatellites are considered for official recognition (Table 1, Fig. 1). Recently the family *Tolecusatellitidae* has been created to host betasatellites and deltasatellites. The word *Tolecusatellitidae* is coined from the first ever identified satellite in Australia (Tomato leaf curl virus-satellite). The nomenclature of betasatellites and deltasatellites species names is so far based on the name of the first helper geminivirus with which the satellite was identified, complemented, if necessary, with the geographical location of the first sample and a number if several species are identified on the same host with the same helper geminivirus. The family encompasses two genera, *Betasatellite* and *Deltasatellite*, and *Ageratum yellow vein betasatellite* and *Tomato leaf curl deltasatellite* are the type species for each genus respectively. Betasatellites and deltasatellites do not share any sequence similarity to each other nor with their helper viruses, except the nonanucleotide origin of replication (TAATATTAC).

Genome Organization

All the known betasatellites have conserved sequence features with an A-rich region (~160–280 nt), a satellite conserved region (SCR, ~80 nt) and a single open reading frame (ORF) coding for a protein called β C1 (~13.6 kDa) (Fig. 2). While deltasatellites lack the β C1 gene and are roughly half the size (~700 nt) of betasatellites (Fig. 2). The A-rich region is involved in the maintenance of betasatellite integrity, as its deletion can cause milder symptoms in the host plant. SCR is involved in interaction with the Rep protein of the helper virus, while β C1 is a multifunctional pathogenicity determinant protein, which interacts with several host factors to counter the host defense system by suppressing both transcriptional and post-transcriptional gene silencing. Deltasatellite do not code for any functional protein and are fully dependent on their helper virus.

Genetic Diversity and Center of Origin for Betasatellites

Betasatellites are widely distributed in the Old World mainly with monopartite begomoviruses. Due to the lack of sequence similarity with their helper viruses or other related viruses, the origin of betasatellites is unknown. Betasatellites are present in more than

Fig. 1 Phylogenetic trees for betasatellites and deltasatellites in the family *Tolecosatellitidae*. The acronyms are listed in Table 1. Betasatellites have ~61 recognized species and 11 putative unassigned species (noted with *), while deltasatellites consist of 11 different recognized species. The reference sequences of each species were downloaded and aligned in MEGA software. The alignment was made through Clustal-W. Phylogenetic trees were constructed by neighbor joining method with 1000 bootstrap replications, and only scores above 50% were noted.

Fig. 2 Genome organization (left to right) of betasatellites and deltasatellites. Betasatellites are of ~1350 nt, with an A-rich region, a satellite conserved region and a small gene $\beta C1$. While, deltasatellites are of ~680 nt and do not encode any gene. The genome organizations of Tomato leaf curl deltasatellites (ToLCD) from Australia, Sweet potato leaf curl deltasatellite-1 (SPLCD-1) and Tomato yellow leaf curl distortion deltasatellite (ToYLCDD-1) from Cuba are presented. The nucleotides region mentioned with magenta colors represent the satellite-conserved region; brown color represents the A-rich region, while green parts represent the secondary stem loop in the sequence.

Fig. 3 Worldwide distribution for 61 species and 11 putative species of betasatellites and 11 species of deltasatellites. Most of the betasatellites species are present in the Indian sub-continent, while a second center of diversity appears in China and Japan. Betasatellites are limited to the Old World, while deltasatellites are present in both the Old World and the New World. (mentioned with *).

20 countries of Asia, Africa, and Europe and none have been identified in the New World (Fig. 3). Potentially, there are ~73 betasatellite species and they mostly belong to South, East, South East, and West Asia (67/73). Among these betasatellites, 35 species circulate in India, Pakistan, Bangladesh, Sri Lanka, and Nepal. While 19 betasatellite species are present in China and Japan. Another 11 distinct betasatellite species exist in Vietnam, Laos, Philippines, Singapore, Indonesia, and Malaysia. In addition, two different species infect okra and tomatoes in Oman and Yemen respectively. The whole African continent only hosts 5 different species of betasatellites that are phylogenetically close to the Oman and Yemen isolates (Fig. 1). While from Europe (United Kingdom) a single betasatellite species is known which was most probably imported from Japan (Fig. 1). A phylogenetic study carried with representatives of these 63 species reveals a very strong geographical distribution with 11 clusters almost 100% homogeneous for the regions mentioned above. Five clusters belong to the Indian subcontinent, 3 to the China-Japan region, 2 from south east Asia and 1 from Africa. Only 11 species are “misplaced” for having a perfect match. Therefore, considering the genetic diversity here described it can be concluded that the Indian sub-continent is possibly the center of origin of betasatellites (Figs. 1 and 3).

Fig. 4 Impact of betasatellite on symptom severity in *Nicotiana benthamiana* plants. The *Nicotiana benthamiana* plants inoculated with Cotton leaf curl Multan virus DNA-A alone show very mild symptoms (center), while the addition of the Cotton leaf curl Multan betasatellite induces very severe symptoms (right). Non-inoculated control plants are on the left.

Unlike betasatellites, deltasatellites have been also identified in the New World (Fig. 3), however it is believed that they were introduced through infected root crops such as sweet potato. A contrario to betasatellites, It is unclear what is the competitive advantage for the helper geminivirus to carry a deltasatellite along. Recent studies suggest that deltasatellites may reduce the geminivirus impact and thereby extend the life of the infected plant, thus allowing a greater period for the geminivirus transmission and survival of the host.

Life Cycle, Epidemiology

As mentioned earlier, the betasatellites are often found with monopartite begomoviruses. However, they are also found in combination with bipartite viruses such as Tomato leaf curl New Delhi virus, Tomato leaf curl Gujarat virus, and Sri Lankan cassava mosaic virus. In the laboratory conditions, betasatellites can also interact with the New World bipartite begomoviruses. Betasatellites are also known to interact with mastreviruses in wheat plants. These observations suggest that trans-replication of betasatellites is not very stringent in respect to the helper geminivirus. The experiments conducted on many economically important begomoviruses suggested that DNA-A alone could effectively produce the disease symptoms in *Nicotiana benthamiana* plants. However, in many other cases, like cotton leaf curl disease, Ageratum yellow vein virus and Eupatorium yellow vein virus, the betasatellites were necessary to induce the disease symptoms (Fig. 4). Further experiments suggested that the role of $\beta C1$ was important for disease induction. A mutated $\beta C1$ could not induce the proper disease symptoms in the inoculated plants, despite of its successful replication in the systemic leaves. The co-inoculation of betasatellite with bipartite begomoviruses like Tomato leaf curl New Delhi virus and Tomato leaf curl Gujarat virus resulted in increased viral titer and exacerbated symptoms. The presence of betasatellites in non-cultivated cotton species did not result in increased symptoms. Therefore it can be concluded that betasatellites result in severe disease symptoms in cultivated crops.

Normally bipartite begomoviruses are accompanied by a DNA-B component, which provides the cell-to-cell movement functions for the virus. The experiments conducted on Sri Lankan cassava mosaic virus and Tomato leaf curl New Delhi virus suggested that betasatellites could make DNA-B dispensable to the helper virus. The exact mechanism of virus movement in the absence of DNA-B is unknown. There are however few indirect evidences, which suggest the possible role of $\beta C1$ encoded by betasatellite in viral movement. The green florescent protein (GFP) tagged to $\beta C1$ of TYLCCNB and CLCMulB were transiently expressed in tobacco cells. The $\beta C1$ accumulated inside the nucleus and the cell periphery, suggesting its possible role in transport of DNA from nucleus to plasmodesmata. However so far, all the experiments for DNA-B replacement were conducted in laboratory conditions, and there is no such example in nature, where a bipartite virus was converted into monopartite virus by capturing a betasatellite, while loosing its DNA-B component. However, there are recent examples, where a cognate betasatellite was replaced by a non-cognate one. For examples, Tomato leaf curl Karnataka virus in India adopted Cotton leaf curl Multan betasatellite replacing Tomato leaf curl Karnataka betasatellite. TYLCV-IR is a monopartite begomovirus in the Middle East, but in Oman, it captured Tomato leaf curl betasatellite. A similar example of re-assortment also exists in Mali, where Cotton leaf curl Gezira betasatellite was found in combination with the monopartite Tomato yellow leaf curl Mali virus.

Replication of Betasatellites

The viruses belonging to family *Geminiviridae* multiply through rolling circle replication (RCR) mechanism. RCR starts by the binding of the Replication associated protein (Rep) at iteron sequences present at the upstream of the nonanucleotide origin of replication. Despite using the same Rep the trans-replication of betasatellites is very relaxed as compared to DNA-B component. A single betasatellite can be trans-replicated by several helper viruses. For example, Cotton leaf curl Multan betasatellite (CLCMulB) can be

maintained in *Nicotiana benthamiana* plants by Ageratum yellow vein virus and Eupatorium yellow vein virus, but Cotton leaf curl Multan virus shows specificity to its cognate betasatellite. The SCR of betasatellites present in the upstream of origin of replication appears to be the analogous of the common region of DNA-A components. As a matter of fact all the defective betasatellites or deltasatellites contain intact SCR indicating its vital role in their replication. The experiments conducted on Tomato leaf curl virus associated betasatellites suggested that the stem loop structure and the satellite conserved region are very crucial sequences for their replication. The betasatellites contain a primary stem loop structure (common to all geminiviruses) and a secondary stem loop structure ~380 nt upstream of origin of replication. The Rep binding affinity experiments suggested that the secondary stem loop structure is very crucial for betasatellites replication as its deletion can cause impaired replication. Despite of their relaxed trans-replication betasatellites have certain unknown specificities with their helper begomoviruses. The Rep binding affinity experiments suggested that helper components have better adaptation with their cognate betasatellites compared to non-cognate ones.

Functional Role of β C1 in Disease Development

The betasatellites strongly influence the pathogenicity of the helper begomovirus. The presence of betasatellites are resulting in very severe disease symptoms. The β C1 gene present in the complementary strand of betasatellite genomes encodes an important pathogenicity determinant protein for geminiviruses of the Old World. Most of the available information regarding β C1 is obtained from Tomato yellow leaf curl china betasatellite (TYLCCNB). The β C1 of TYLCCNB localizes in the nucleus and forms a multimeric complex due to two alpha helices present at the C-terminus of the protein. The self-interaction of β C1 is important to induce the disease symptoms. Indeed, a mutated version of β C1, that cannot make a multimeric complex, is unable to induce the typical disease symptoms. The nuclear localizing signal (NLS) of β C1 is also important in the disease induction. The deletion mutants for NLS in TYLCCNB resulted in its inability to induce typical disease symptoms.

The protein β C1 is a multitasking protein, which suppresses the transcriptional and post-transcriptional gene silencing, the whole hormone based defense system, and the ubiquitin proteome degradation system. It also inhibits the activity of kinases like mitogen activated protein kinases (MAPK). The pleiotropic interaction of β C1 with multiple pathways results in enhanced virulence and infection. The transgenic plants expressing the protein β C1 show severe disease-like symptoms. In the infected cells, β C1 interacts with the Asymmetric Leaves gene 1 (AS1), which can ultimately result in suppression of jasmonic acid (JA) production and its associated genes. The suppression of JA results in severe disease symptoms. The β C1 encoded by Radish leaf curl betasatellite (RaLCB) localizes in chloroplast and results in vein clearing symptoms. The symptoms were very severe in the presence of Tomato leaf curl New Delhi virus. The detailed biochemical analysis revealed that β C1 altered the starch accumulation, decreased the thylakoid contents and change the granum structure. β C1 counters the gene silencing initiated by plants as a defense against betasatellite and geminiviruses. The interaction of β C1 with Calmodulin-like (CaM-endogenous suppressors of gene silencing) proteins results in higher accumulation of the helper virus by compromising the RDR6 based gene silencing. β C1 is also a target of the ubiquitination based protein degradation pathway. It has evolved a system to hijack the ubiquitination machinery. The interaction of β C1 with host proteins resulting in reduction of polyubiquitinated proteins. Autophagy is another evolutionary conserved pathway, which is targeted by β C1. Autophagy is actively involved in controlling several viruses. Studies have shown that, autophagy pathways targeted and degraded the β C1. The silencing of autophagy related genes; *ATG5* and *ATG7* resulted in increased susceptibility to begomoviruses and betasatellites.

Resistance Against Betasatellites

So far, there is no example where geminiviruses/betasatellites have been controlled successfully at commercial level. However, limited success has been reported at the experimental levels. During the natural infection tobacco ring finger proteins (RFP- a functional E3 ubiquitin ligase) ubiquitinates and degrades the β C1 proteins. The impact of β C1 ubiquitination can be observed by attenuated symptoms. In the future, it is believed that exploiting such pathways to increase the plants immunity level against geminiviruses/betasatellites complexes, is possible. Recent studies conducted on Tomato yellow leaf curl virus demonstrated that *Ty-1* gene confers natural resistance against the virus. However, with the addition of a betasatellite the *Ty-1* based resistance was compromised and viral titer was increased. Due to the global spread of betasatellites the coordinated efforts between different countries are required.

Deltasatellites

Introduction

Deltasatellites were the first satellites identified with an example from Australia in association with Tomato leaf curl virus (ToLCV). Initially it was named ToLCV-Sat, but now it has been renamed as Tomato leaf curl deltasatellite (ToLCD). The ToLCD (682 nt long) did not share any significant sequence identity with the helper virus except for the origin of replication. The sequence variability of ToLCD is unknown due to the lack of sequences available in the GenBank. The ToLCD can be maintained by very distinct geminiviruses including Tomato yellow leaf curl Sardinia virus, African cassava mosaic virus and Beet curly top virus. From the New World, deltasatellites were first reported in 2012 from the Caribbean islands. To date, deltasatellites are known from India, Vietnam, Philippines, Spain, Australia, Cuba, and Puerto Rico. There are 11 distinct species of deltasatellites, which are phylogenetically not linked to each other (Table 1, Fig. 1).

Genome Organization of Deltasatellites

Deltasatellites do not encode any gene in their genomes. However, they share some common features. Most of the known deltasatellites contain a variable A-rich region, a nonanucleotide origin of replication (TAATATTAC) and a secondary stem loop structure. The deltasatellites from Australia and Spain, share common features of A-rich region and a satellite conserved region. However, the deltasatellites from the New World have very short satellite conserved region (**Fig. 2**).

Trans-Replication of Deltasatellites

Deltasatellites are not self-replicating molecules therefore they require helper viruses for their replication and systemic movement. Although, ToLCD can be maintained by several heterologous Old World geminiviruses, but it does not contribute to any symptom severity or increase of the helper virus titer. The experiments conducted on New World deltasatellites suggested that they cannot be trans-replicated by Old World begomoviruses or curtoviruses, however they can be efficiently maintained by New World bipartite and monopartite begomoviruses. Deltasatellites significantly reduce their helper component's accumulation. Deltasatellites do not encode any gene in their genome, therefore the biological significance and mode of action of deltasatellites is clearly not understood.

Glossary

Cytopathology The study of disease at the cellular level.

Symptomatology The symptom complex of a disease.

Introduction

Kitaviridae is a family of positive-sense RNA viruses with linear, segmented genomes and bacilliform to spherical virions. All current members of the family infect plants, often causing chlorotic and/or necrotic lesions in their natural hosts. These infections are typically non-systemic, making them highly unusual among plant viruses. Despite being non-systemic, diseases caused by these viruses can be highly destructive and of tremendous economic importance, with citrus leprosis being the most prominent. Citrus leprosis virus C, a causal agent of citrus leprosis, represents the most well-studied member and functional model for the family. The name *Kitaviridae* is derived from the renowned Brazilian virologist and electron microscopist Dr. Elliot W. Kitajima, in recognition of his extensive contributions to our knowledge on the fundamental aspects of kitavirus structure, cytopathology, and biology. The family was established by the International Committee on Taxonomy of Viruses (ICTV) in 2018.

Taxonomy, Phylogeny, and Evolution

The family *Kitaviridae* is currently composed of three genera, established by the ICTV, *Cilevirus*, *Higrevirus*, and *Blunervirus*. The genus *Cilevirus* derives its name from the type species *Citrus leprosis virus C*, the prevalent causal agent of citrus leprosis, one of the most aggressive and important citrus diseases in South and Central America. The genus *Higrevirus* is named after the type species *Hibiscus green spot virus 2* (HGSV 2), a virus associated with leprosis-like lesions in some citrus species and chlorotic lesions on the leaves of hibiscus species. To date, the virus and its associated diseases have only been reported in the Hawaiian Islands. The genus *Blunervirus* was named after its type species *Blueberry necrotic ring blotch virus*, which was discovered in 2010 from symptomatic highbush blueberry (*Vaccinium corymbosum*) plants in Georgia, United States. At the species level, demarcation criteria have only been established for the genus *Cilevirus* and include the extent of serological relationship; <85% amino acid identity for the proteome, natural and experimental host range reactions, and vector species and transmission. Recently, a threshold of 75% amino acid identity for the polyprotein encoded by RNA1 has been proposed for species demarcation in the genus *Blunervirus*.

Phylogenetic reconstructions using RNA-dependent RNA polymerase (RdRp) sequences, the standard for inferring relationships between RNA viruses, illustrate the family *Kitaviridae* as a monophyletic clade and sister taxon to the plant virus family *Virgaviridae*. The phylogenetic relationships that kitaviruses share with other viral taxa, however, are not this straightforward. For example, blueberry necrotic ring blotch virus (BNRBV) encodes two helicase (HEL) domains. Phylogenetic reconstructions using these two domains indicate that one (HEL-1) is most closely related to those of virgaviruses, and the other (HEL-2) most closely related to members of the plant virus family *Bromoviridae*. Furthermore, the methyltransferase (MTR) domain of BNRBV contains hallmark motifs that are found in bromoviruses. The predicted movement proteins (MP) of kitaviruses are also of different phylogenetic lineages, with blunerviruses and cileviruses possessing 3A MPs of the 30K superfamily, and the lone higrevirus possessing 'triple gene block' MPs. Taken together, the evolutionary history of kitaviruses is complex and highly indicative of recombination events between distinct viral taxa.

High-throughput metagenomic sequencing of arthropod and other invertebrate specimens has provided evidence of several unclassified viruses that appear to be closely related (and even interspersed) within the kitavirus clade when using the RdRp as the phylogenetic signal. Furthermore, a predicted structural protein designated p22 (*Blunervirus*), p23 (*Higrevirus*) or p24 (*Cilevirus*) is present in all kitaviruses (but no other plant virus taxa), and also in some of these unclassified invertebrate viruses (Fig. 1). This, combined with the inability of recognized kitaviruses to infect their natural plant host systemically, has led to speculation that the evolutionary progenitor(s) of the kitavirus clade might be an arthropod virus.

Members of the Family

The family *Kitaviridae* is sparsely populated, with only four recognized species among the three genera. Some tentative members have been partially described but are not currently recognized by the ICTV (Table 1).

Fig. 1 Phylogenetic relationships across kitaviruses (BNRBV, HGSV-2 and CILV-C) and unclassified invertebrate viruses, based on hypothetical protein p22–24. A Bayesian tree is shown using LG + G + I protein evolution model. NCBI (National Center for Biotechnology Information) accession numbers are provided on the right. Taxa where p22–24 have been annotated as host proteins are indicated by the asterisk (*).

Table 1 Species and tentative species in the family *Kitaviridae*

Virus	Genomic segments	Genome length (kb)	Natural host
Genus <i>Blunervirus</i>			
Definitive species			
<i>Blueberry necrotic ring blotch virus</i> ^a	4	14.15	Blueberry
Tentative species			
Tea plant necrotic ring blotch virus	4	15.08	Tea
Genus <i>Cilevirus</i>			
Definitive species			
<i>Citrus leprosis virus C</i> ^a	2	13.73	Citrus, tropical spiderwort (<i>Commelina benghalensis</i>)
<i>Citrus leprosis virus C2</i>	2	13.71	Citrus, hibiscus
Tentative species			
Ligustrum ringspot virus	N/a	N/a	Privet
Passion fruit green spot virus	N/a	N/a	Passion fruit
Genus <i>Higraviruses</i>			
Definitive species			
<i>Hibiscus green spot virus 2</i> ^a	3	14.70	Citrus, hibiscus

^aType species.

Virion Structure

Virion morphology for members of the *Cilevirus* and *Higraviruses* genera has been determined by transmission electron microscopy (TEM). Infected cells contain congregations of bacilliform virions, which are typically detected in cytoplasmic vesicles associated with the endoplasmic reticulum. Virions range between 30 and 50 nm in width and 50–120 nm in length depending on the species (Fig. 2). Electron microscopy studies have not been done to investigate virion morphology of BNRBV (genus *Blunervirus*). However, TEM examination of ultrathin sections of symptomatic tissue infected with tea plant necrotic ring blotch virus, a proposed member of the genus, revealed cytoplasmic aggregates of spherical virus-like particles approximately 85 nm in diameter.

Fig. 2 Transmission electron micrographs of ultrathin sections of soybean (an experimental host) leaves infected with Citrus leprosis virus C (CiLV-C). Asterisk (*) indicates electron-dense viroplasm, and arrows show host-derived vesicle structures containing virus-like particles. Photo courtesy of Dr. E.W. Kitajima.

Genome Organization and Gene Product Function

Kitavirus genomes are multipartite and composed of linear, positive-sense RNA molecules (Fig. 3). The genomes of current cileviruses are bipartite and comprise a total length of 13.1 kb. RNA1 contains a large 5'-terminal open reading frame that encodes a replication-associated polyprotein containing MTR, HEL, and RdRp domains followed by an ORF encoding a 29 kDa protein predicted to be the capsid protein (CP). Homologs of this putative CP have not been found in other kitavirus genomes. RNA2 contains four ORFs, the first of which encodes p15, which appears to have a role in cellular remodeling for vesicle formation. The second ORF encodes p61, a predicted glycoprotein that also appears to remodel the host endoplasmic reticulum (ER). The third ORF encodes a 3A type MP, and the 3'-terminal ORF encodes p24, a predicted virion membrane protein. p24 is one of the few proteins encoded by all kitaviruses and is also present in some unclassified invertebrate viruses. The 5'-termini of the RNAs are capped and the 3'-termini are polyadenylated.

The genome of the current higrevirus species is tripartite and comprises a total length of 14.7 kb. RNA1 is similar to that of cileviruses but lacks the putative 29 kDa CP. RNA2 possesses a 50 kDa protein of unknown function followed by a triple gene block-like suite of proteins of 39, 9, and 6 kDa which putatively serves as the MPs of the virus. However, recent findings have suggested that proteins p39 and p9, acting in a 'binary movement block', are sufficient for virus intercellular movement. RNA3 possesses three ORFs of 33, 29, and 23 kDa. The first two are of unknown function, and p23 is a homolog of the cilevirus p24 and blunervirus p22. Higrevirus RNAs are polyadenylated on their 3'-termini.

Current blunervirus genomes are quadripartite and comprise a total length of 14.2 kb. RNA1 contains a single open reading frame (ORF), whose predicted protein contains MTR and HEL-1 domains. The single ORF predicted in RNA2 encodes the putative RdRp, with the HEL-2 domain at the N terminus. RNA3 comprises five short ORFs (ORF3a, 3b, 3c, 3d and 3e) putatively encoding proteins of unknown functions. One of these unknown proteins, p22, encoded by ORF3c, has homology to proteins of similar size in cileviruses (p24), higreviruses (p23) and unclassified invertebrate viruses. RNA4 has a single ORF coding for the putative MP, which possesses motifs conserved with the 3A family of the 30K superfamily of viral MPs (30Ksf). This protein is homologous to its counterpart in cileviruses. Non-coding regions (NCR) at 5'-ends vary in size, with an unusually long (> 350 nt) NCR in RNA4. NCRs at 3'-ends of BNRBV contain conserved nucleotide stretches. Although the presence of poly (A) tails were not documented for the original BNRBV genome, adenosine stretches of varying size were detected on 3'-termini of BNRBV-RL (a red-lesion strain discovered in Florida) and the putative new blunervirus Tea plant necrotic ring blotch virus (TPNRBV); suggesting that polyadenylation is a common feature in kitaviruses.

Replication and Propagation

The Cilevirus citrus leprosis virus C (CiLV-C) represents the most well-studied kitavirus and the main virus for which replication and propagation studies have been conducted. Some information on that regard has been obtained for Citrus leprosis virus C2 as well (CiLV-C2). CiLV-C RNA replication-associated proteins (MTR, HEL, and RdRp) are expressed from genomic RNA1 as a polyprotein. Other proteins involved with replication and propagation are expressed via 3'-terminal sub-genomic RNAs. Replication appears to occur in cytoplasmic vesicles formed through the modification of cortical endoplasmic reticulum (ER) by

Fig. 3 Genomic organization of the type species for each genus in the family *Kitaviridae*. Boxes represent open reading frames (ORFs). ORFs are labeled with either the predicted molecular weight (kDa) of the protein product, or its function: MTR, methyltransferase; HEL, helicase; RdRp, RNA-dependent RNA polymerase; and MP, movement protein. Asterisk (*) indicates that the polyadenylated 3'-terminus has been reported for one isolate of the blueberry necrotic ring blotch virus, but not another. The scale at top represents approximate RNA length in kilobases (kb).

multiple virus-encoded proteins. Transfer of virus replication complexes and/or the viral ribonucleoproteins from the cytoplasmic vesicles to plasmodesmata may be facilitated by actin or ER trafficking. Viral MP then facilitate cell-to-cell movement through the plasmodesmata. Only non-systemic movement has been reported for any member of the family in plant hosts, although systemic movement has been shown for TPNRBV.

Transmission and Host Range

Cileviruses are vectored by polyphagous mites in the genus *Brevipalpus* in a persistent manner. There is molecular evidence for replication in these mites, but this has not been confirmed by electron microscopy, despite extensive efforts. Preliminary transmission studies indicate higreviruses are also transmitted by brevipalpus mites. Cileviruses and higreviruses have been found to naturally infect *Citrus* and *Hibiscus* spp., and experimental host range experiments using viruliferous mites have demonstrated that CiLV-C is able to infect dozens of plant species, including several of economic importance such as common bean and soybean.

Preliminary transmission experiments, both under field and greenhouse conditions, have demonstrated that the blunervirus BNRBV is transmitted by eriophyoid mites in the genus *Calacarus*. The specific mechanism by which the vector transmits the virus is not known. BNRBV has not been reported in any host other than highbush blueberry. TPNRBV, a putative blunervirus, was found to infect tea plants (*Camellia sinensis*), although no additional transmission or host range data is currently available.

Diseases, Epidemiology, and Control

Citrus leprosis disease has multiple causal agents, including CiLV-C and CiLV-C2, which are both members of the genus *Cilevirus*. Symptoms of infection include localized chlorotic and necrotic lesions on both leaves and fruit, which can lead to premature abscission. Citrus leprosis is extant only in South and Central American countries. Although historical reports of the disease in Florida, USA exist, it appears the pathogen at this location was an unrelated virus which causes nearly identical symptoms in citrus. In Brazil, citrus leprosis caused primarily by CiLV-C is often regarded as the most important virus disease of citrus. Management efforts to control the disease, which are primarily the application of acaricides to control vector populations, often reach \$40–80 M USD per year.

In Hawaii, the higrevirus Hibiscus green spot virus 2 (HGSV-2) is responsible for an isolated disease on some citrus varieties that resembles citrus leprosis. Unlike citrus leprosis, foliar lesions on citrus caused by HGSV-2 rarely become necrotic, and lesions on fruit are only visible on green, unripe fruit. HGSV-2 also causes lesions on hibiscus leaves which are most prominent during senescence. Severe infection may cause premature abscission of leaves which may be of concern to threatened and endangered hibiscus species native to Hawaii.

The blunervirus BNRBV was discovered as the causal agent of an unusual disease observed in southern highbush blueberry (*Vaccinium corymbosum* interspecific hybrids) plantings in Georgia, USA. Infected plants display irregularly shaped rings on the adaxial and abaxial leaf surfaces, which coalesce to form brown-to-black necrotic blotches, followed by premature defoliation. Since its first report in 2006, the disorder has become commonplace in other southern states including Florida, Mississippi, North Carolina and South Carolina. In Florida, a variant of the virus was characterized and found to induce red concentric rings, which develop across leaves without turning into necrotic spots or falling out prematurely. This strain is referred to as BNRBV-red lesion (RL) and shares an overall 90% nucleotide identity with BNRBV. The impact of the disease caused by BNRBV has not been reported.

None of the current kitaviruses can move systemically in plant hosts and are therefore not graft-transmissible. However, stem lesions or viruliferous mites present on propagative materials can serve as a reservoir for long-distant movement by humans. Unlike citrus and hibiscus, blueberry defoliates in winter, indicating a direct role of overwintering vectors and/or alternate (virus reservoir) hosts in the spread of BNRBV during subsequent seasons. This aspect of the virus life cycle has a direct implication in terms of disease management by controlling the vector.

Diagnosis

Determining the localization of virions and viroplasm by TEM was initially used to distinguish the cytoplasmic citrus leprosis viruses (CiLV-C and CiLV-C2) from the unrelated nuclear virus which caused similar symptoms. Today, PCR-based molecular approaches are used for kitavirus detection. Serological detection approaches are also available for CiLV-C and CiLV-C2, which include enzyme-linked immunosorbent assays (ELISA) and cellular analysis and notification of antigen risks and yields (CANARY) platforms.

Concluding Remarks

The kitaviruses are a small, but important group of emerging viruses that warrant study not only for control of the diseases they cause, but also to better understand the fundamentals of plant virology. The non-systemic nature of their infection opens intriguing opportunities for experimentation on virus movement and arthropod vector relationships. The putatively close evolutionary relationship with a growing number of unclassified invertebrate viruses suggests that in the future this taxon may not be restricted to plant viruses.

Glossary

Host factor Host proteins, lipids, and metabolites subverted by the virus at multiple stages of the life cycle required for successful viral infection.

Spherule Single-membrane vesicular invaginations of host membranes induced by positive-strand RNA viruses in which viral replication proteins, RNA templates, and specific host factors are enriched and viral genome replication takes place. Other names used to refer to RNA replication competent spherules are viral replication compartments,

viral replication complexes, or viral replication mini-organelles.

Sub-genomic RNA A messenger RNA produced during viral replication to express downstream viral genes from a viral genomic RNA expressing multiple genes.

Tripartite RNA genome The viral genome is composed of three pieces of RNAs, which are all required for a successful systemic infection, may differ in length and in viral proteins encoded but may share similar sequences and/or structures of untranslated regions as well as 5' and/or 3' ends.

Introduction

Brome mosaic virus (BMV) is a positive-strand RNA virus that infects cereal plants, causing mosaic symptoms and stunting. BMV is the type member of the genus *Bromovirus* in the family *Bromoviridae*. BMV is also a representative member of the alphavirus-like super-family that include viruses infecting human, animal, and plants that share similar genome structures, gene expression strategies, and protein functions. BMV has been used as a model to study gene expression, RNA replication, virus-host interactions, recombination, and encapsidation by positive-strand RNA viruses. Major contributions have revealed insights and principles extending to many other viruses and to general cell biology. Among numerous advances, research in BMV defined the first ribosome binding sites in eukaryotic mRNAs, produced the first eukaryotic viral RNA-dependent RNA polymerase (RdRp) extract that was template specific, the first infectious transcripts from cloned cDNA, the first engineered RNA virus expression vector expressing foreign genes, the first definition of sub-genomic mRNA synthesis pathways and determinants, and the first demonstration of higher eukaryotic viral replication in yeast. BMV has contributed many insights into virion assembly, virus-host interactions, RNA recombination, and RNA replication, including parallels in the replication of positive-strand RNA, reverse-transcribing and dsRNA viruses.

Virion Structure and RNA Encapsidation

BMV forms non-enveloped virions ~28 nm in diameter. The outer capsid is composed of 180 copies of coat protein (CP) arranged with $T = 3$ quasi-icosahedral symmetry. Cryo-electron microscope reconstructions and subsequently x-ray crystallography showed that the BMV capsid structure is extremely similar to that of the related bromovirus Cowpea chlorotic mottle virus (CCMV). Intriguingly, some features of these capsids are dissimilar from other known isometric RNA virus capsids, but similar to capsids of the DNA-

Fig. 1 Organization of the Brome mosaic virus (BMV) RNA genome. BMV has three genomic RNAs, RNA1, RNA2, and RNA3, and a sub-genomic mRNA, RNA4, encoded by the 3' portion of RNA3 as shown. Each of these four BMV positive-strand RNAs bears a 5' m⁷G cap and 3' tRNA-like structure (cloverleaf). The recruitment element (RE) in each viral genomic RNA and the promoter of sub-genomic RNA4 (Pro_{sgRNA}) in RNA3 are shown. Open boxes represent the genes for the viral proteins 1a and 2a^{pol}, which are required for RNA replication, and 3a and coat protein, which are required for systemic movement in host plants. Some specific functions and features of each viral protein are listed, including the amphipathic α -helices at the N-terminus of 1a. The N-terminus (bottom half) and C-terminus (top half) of 1a are labeled as N and C, respectively. BMV 1a interacts with 2a^{pol} via the C-terminus of 1a and the N-terminus of 2a^{pol}.

containing papovaviruses. These features include orientation of the core β -barrel nearly perpendicular to the capsid surface to form distinctively prominent hexameric and pentameric capsomeres, and linking of adjacent capsomere clusters by exchange of invading C-terminal arms. These shared features suggest that BMV CP and the CPs of polyoma- and papillomaviruses likely share a common ancestor. BMV virion RNA is arranged as an interior subshell inside the capsid, leaving a hollow virion center. The N-terminal 26 aa of the CP, which are highly basic and required for RNA packaging, interact with the RNA to neutralize its charge.

In addition to the predominant 180-subunit capsid, BMV CP can also assemble *in vivo* a 120-subunit capsid, composed of 60 CP dimers, first discovered in yeast and subsequently confirmed in infected plants. This assembly polymorphism is controlled *in vivo* by the RNA packaged, with BMV RNA2 packaged in 180-subunit capsids, while a small chimeric mRNA containing the CP open reading frame (ORF) as its only BMV sequence is packaged in 120-subunit capsids. Structural features shared by 120- and 180-subunit capsids imply that a common pentamer of CP dimers is an important intermediate in BMV virion assembly.

In vitro and *in vivo* encapsidation identified portions of the BMV 3a coding region whose deletion blocked RNA3 encapsidation and interfered with normal co-encapsidation of RNA3 and RNA4. Studies also implicated the 3' tRNA-like structure of BMV RNAs as a facilitator of encapsidation *in cis* or *trans*, possibly by nucleating CP interactions into productive assemblies such as pentamers of dimers, and showed that BMV RNA replication promotes selective encapsidation of viral RNAs, possibly by inducing coupled synthesis of viral RNA and CP in close proximity.

In 1971, buoyant density gradients were used to separate BMV virions into three classes, all three have identical capsids but package different RNAs (Fig. 1). Heavy virions contain a single copy of RNA1 (3.2 kb), medium density virions contain one copy each of RNA3 (2.1 kb) and RNA4 (0.9 kb), and light virions contain a single copy of RNA2 (2.9 kb). The three classes of viral particles are indistinguishable by electron microscopy, however, distinct capsid-RNA contacts influence the stability of the virions, viral RNA release, and BMV infection. Mapping of the contacts made between CP and the viral RNAs showed that RNA1 contacts CP differently than RNA2 or RNA3/4. Virions containing RNA1 were more sensitive to protease digestion and treatment of virions with RNase A revealed that RNA1 was preferentially degraded, while RNA2 or RNA3/4 were more resistant to RNase A digestion. The more facile interaction between RNA1 and the capsid proteins could ensure earlier and higher expression of BMV 1a, which is responsible for the formation of the viral replication compartments (see below in the Section of "Properties and Functions of Viral Gene Products"). The interaction of the viral RNAs with capsid is also influenced by the phosphorylation state of the N-terminal arm of the capsid protein. Interestingly, virions produced from different plant hosts had different post-translational modifications that impacted the thermostability of virions as well as the capsid-RNA interactions.

Genome Organization

Genome Structure, Gene Expression and Sequences

Interest in characterizing the protein(s) encoded by each of the four BMV virion RNAs motivated early *in vitro* translation studies with purified BMV virion RNAs. RNAs 1, 2, and 4 were characterized as monocistronic while RNA3 is dicistronic. Although early

infectivity studies showed that RNA3 encodes CP, tryptic analysis showed that the principle translation product of RNA3 was unrelated to CP, while RNA4 served as an excellent template for CP. Moreover, when mixtures of all BMV RNAs were added to wheat germ extracts, increasing amounts of RNA4 inhibited translation of genomic RNAs 1–3. These results showed that RNA4 is a sub-genomic CP mRNA derived from RNA3, and implied an elegant system of gene regulation by translational competition: early in infection when viral RNA concentrations are low, all viral proteins including nonstructural RNA replication factors are translated, while after the virion RNAs are sufficiently amplified, CP is preferentially translated to encapsidate these RNAs.

By the early 1970s, RNA bacteriophage studies had provided valuable information on prokaryotic translation initiation sites, including the finding that the first AUG initiation codon usually was 100 or more nucleotides from the RNA 5' end. In 1975, the first eukaryotic translation initiation site was characterized by isolating two fragments of BMV RNA4 that were efficiently bound by wheat germ ribosomes. RNA sequencing (a challenging, chromatography-based process at the time) revealed that the two fragments were 5' terminal, overlapping, and encoded the first 4 and 14 aa of CP, respectively. The most distinguishing feature was that the initiating AUG codon for CP began only 10 nucleotides from the m⁷G^{5'}ppp^{5'}Gp-capped RNA4 5' end, presaging the now well-known mechanistic linkage between most eukaryotic translation initiation and 5' mRNA caps.

The ~8.2 kb BMV genome sequence was completed in 1984. In good agreement with *in vitro* translation results, RNA1 and RNA2 encode single proteins 1a (109 kDa) and 2a (94 kDa), respectively, the 5' half of RNA3 encodes protein 3a (35 kDa), and the 3' half of RNA3 encodes for RNA4, the sub-genomic mRNA for CP (20 kDa) (Fig. 1). Later work discussed below showed that 3a is required for infection movement in plants. Comparisons with other emerging viral RNA and protein sequences quickly revealed that the BMV 1a and 2a proteins, already implicated in RNA replication by protoplast experiments, shared extensive amino acid sequence similarities with proteins encoded by a diverse set of plant and animal positive-strand RNA viruses. These similarities initially were recognized between BMV, Alfalfa mosaic virus, Tobacco mosaic virus and Sindbis virus, and subsequently were found to extend to many other viruses now grouped together as the alphavirus-like super-family. Similarities shared by these viruses include a polymerase domain in BMV 2a (hereafter 2a^{pol}) and RNA capping and RNA helicase-like domains in 1a (Fig. 1).

Noncoding Regions, *Cis* Signals, and Sub-Genomic Promoter

The first region of BMV RNAs to attract attention as a potential regulatory element was the 3' end. Synergistic work by multiple groups showed that the 3' non-coding regions (NCR) of BMV RNAs are highly conserved, contain multifunctional domains that direct negative-strand RNA synthesis, contribute to RNA encapsidation, translation and stability, and possess multiple tRNA-like features and functions.

Limited early sequence data showed that BMV RNAs 1–4 share a tRNA-like CCA_{OH} 3' end. All four BMV RNAs are selectively amino-acylated *in vitro* with tyrosine. Further studies showed that tyrosylated BMV RNAs interacted with translation elongation factor 1a and that BMV RNAs were tyrosylated *in vivo* during infection of barley protoplasts. BMV RNA 3' ends were also found to interact with (ATP, CTP):tRNA nucleotidyl transferase, which can add 3' CCA_{OH} ends to mature BMV RNAs or maintain incomplete BMV RNAs, thus acting as a primitive telomerase. Beginning in the 1970s, further sequencing, enzymatic structure probing, and three-dimensional computer modeling showed that the 3' ~200 nt of all BMV RNAs were strongly conserved and folded into an extended, tRNA-like structure with at least two alternate forms that differed in pairing nucleotides near the 3' with local or distal partners. Similarly conserved, highly structured 3' regions with related alternate forms were also found in other members of the family *Bromoviridae*.

In vitro and *in vivo* studies using RNA fragments and mutations showed that sequences within the 3'-terminal tRNA-like structure direct negative-strand RNA initiation for RNA replication. Recent results have also implicated the tRNA-like sequence in translation and encapsidation. Involvement in all of these functions led to early and continuing suggestions that the 3' region mediates co-regulation of the varied uses of BMV positive-strand RNAs to minimize conflicts between multiple essential processes.

A second class of elements combining tRNA-like features, replication signals and possible interaction with translation are the BMV template recruitment element (Figs. 1 and 2). Deletion analysis revealed that, in addition to 3' and 5' sequences required for negative- and positive-strand RNA initiation, BMV RNA3 replication *in vivo* requires a segment of ~150 nt in the 5' half of the intergenic non-coding region between the 3a and CP genes (Fig. 1). Subsequent studies showed that this region is required for a step prior to negative-strand RNA synthesis, and is necessary and sufficient for 1a to recognize and recruit an RNA to a membrane-associated, translationally inaccessible, nuclease-resistant state that appears to be the interior of the replication compartments, also known as spherules (see the Section "BMV 1a and Viral Replication Compartments"). Structure probing studies show that this intergenic RNA3 sequence folds into a long, bulged stem-loop, which presents at its apex the invariant sequence and structure of tRNA T Ψ C stem-loops. In plant and yeast cells, the appropriate BMV residues in this consensus are modified to T and Ψ , showing that, like the 3' end, this sequence interacts *in vivo* with tRNA-specific enzymes. Moreover, any mutations to this T Ψ C stem-loop mimicry abolish 1a-mediated template recruitment. Similar stem-loops with apical T Ψ C stem-loop regions are found at the extreme 5' ends of BMV RNA1 and RNA2, where they similarly direct 1a-mediated template recruitment (Fig. 1).

A common approach to express downstream gene(s) in a viral genomic RNA encoding more than one gene is to produce sgRNA(s) efficiently. *In vivo* and *in vitro* analyses of the BMV sub-genomic mRNA promoter have complemented well to reveal a core promoter within the 20 nt immediately upstream of the RNA4 start site, which directs low level but accurate initiation of sub-genomic mRNA. *In vivo*, the activity of this core promoter is greatly enhanced by upstream sequences that include an oligo(A) tract of variable, ~16–22 nt in length in the viral population as well as upstream, partially conserved repeats of core promoter

Fig. 2 Host factors required for the formation of functional BMV spherules. Host genes are involved in every step of BMV genome replication, including viral protein synthesis, recruitment of the viral RNA from ribosomes to the interior of spherules, targeting 1a to the nuclear ER membrane, membrane lipid composition and 1a-membrane interactions, spherule formation, and activation of replication activity. Host genes and pathways whose involvement in viral replication has been well characterized are listed.

sequences. The important role of the oligo(A) tract suggests that while negative-strand RNA can serve as a sub-genomic mRNA template *in vitro*, the natural *in vivo* template might be a dsRNA within which the oligo(A) provides a melting site to facilitate internal initiation.

As one important aspect of *cis* signals in BMV replication, minimal core promoters were defined and dissected for the synthesis of negative-strand, positive-strand, and sub-genomic RNA, using a variety of approaches. Among other results, mutational studies imply that the BMV RdRp-promoter interaction has the characteristics of an induced fit, wherein the RdRp has some tolerance to adjust its binding to a range of promoter variants as long as some key sequence features remain. This model potentially reconciles the specificity of BMV RNA synthesis with the ability of the RdRp to synthesize different forms of viral RNA from separate promoters with distinct primary sequences and secondary structures. DNA or DNA/RNA hybrid templates containing the key BMV promoter sequences can be recognized *in vitro* by BMV RdRp extracts and copied into RNA. Although the efficiency of copying DNA templates is ~15-fold lower than for BMV RNA templates, these results have significant potential implications for virus evolution.

Replication and Propagation

In Vitro and *In Vivo* Replication Studies

Positive-strand RNA viruses, like BMV, replicate their genomes in a completely RNA-dependent manner, producing a negative-strand RNA replication intermediate for each genomic RNA. Studies on BMV RNA replication were greatly advanced by the development and subsequent use of such tools as *in vitro* RdRp extracts and cultured plant protoplasts. In 1979, a virus-specific *in vitro* RdRp extract was developed from BMV-infected barley leaves that synthesized full-length negative-strand RNAs using added BMV virion RNAs as templates. This was the first eukaryotic *in vitro* RdRp preparation exhibiting a high level of template specificity, with other viral RNAs having less than 20% of the template activity of BMV RNAs. As noted in part below, this and similar BMV *in vitro* systems have been utilized to make many advances regarding promoters for positive- and negative-strand RNA synthesis, initiation mechanisms, and other issues.

In parallel to *in vitro* systems, cultured plant protoplasts provided a valuable substrate for *in vivo* replication studies due to their ability to be infected or transfected with nearly 100% efficiency with virions, virion RNAs, or *in vitro* transcripts from cloned viral cDNAs. For BMV, barley protoplast systems have allowed examining all aspects of BMV RNA replication, sub-genomic RNA synthesis, progeny RNA encapsidation, and the like. The highly synchronized infections obtained also allow detailed kinetic studies.

In the early 1990s, it was shown that BMV also would direct RNA replication, sub-genomic RNA synthesis, selective viral RNA encapsidation, RNA recombination and the like in the well-studied yeast, *Saccharomyces cerevisiae*. This host provides some of the same advantages as plant protoplasts together with rapid growth, a particularly small genome, well-characterized gene functions and cell biology, and powerful classical and molecular genetic tools including genome-wide arrays of isogenic yeast strains with each gene systematically modified by deletion, GFP-tagging, etc. Yeast cells expressing BMV RNA replication proteins 1a and 2a^{Pol} support the

replication of BMV genomic RNAs introduced by transfection or DNA-dependent transcription from plasmids or chromosomally integrated expression cassettes, duplicating all major features of replication in plant cells. To facilitate yeast genetic studies, BMV RNA replicons can express selectable or screenable markers and are transmitted to yeast daughter cells during cell division with 85%–90% efficiency, rivaling the transmission of yeast DNA plasmids. Some key findings identified and characterized in the BMV-yeast system have been confirmed in plants, including the enrichment of phosphatidylcholine at the viral replication sites in BMV-infected barley cells and an inhibition of BMV replication in BMV-infected *Nicotiana benthamiana* by overexpressing host gene *PAH1* (Phosphatidic Acid Hydrolase 1) or a dominant-negative mutant of host *SNF7* (Sucrose Non Fermenting 7) (see below in the Section “Host Factors in RNA Replication”). However, it should be noted that there are some differences in the replication features between plant and yeast cells as further discussed in the Section “BMV 1a and Viral Replication Compartments”.

Sub-Genomic mRNA Synthesis

Early observations that the nature of CP in BMV infections is dictated by RNA3 rather than RNA4, and that RNA4 was regenerated when omitted from BMV inoculum, were partially explained when sequencing revealed that RNA4 was encoded by the 3′ portion of RNA3. Nevertheless, whether RNA4 was produced from RNA3 by cleavage or any of several possible RNA synthesis pathways remained uncertain. In 1984, it was shown that a BMV RdRp extract produced sub-genomic RNA4 *in vitro* when supplied with negative-strand RNA3 templates, and that the product RNA4 could be labeled by γ -³²P-GTP incorporation, demonstrating *de novo* initiation. This first elucidation of a pathway for sub-genomic mRNA synthesis appears to provide a meaningful precedent for similar sub-genomic mRNA synthesis by many positive-strand RNA viruses, and an important foundation for understanding the diversity of alternate mechanisms that has begun to emerge with the demonstration of distinctly different sub-genomic mRNA synthesis pathways used by coronaviruses, nodaviruses and some other positive-strand RNA viruses.

RNA Recombination

In 1986, BMV was used to provide an early demonstration of RNA recombination in a plant virus. Subsequent work demonstrated many forms and features of inter- and intra-molecular, homologous and non-homologous RNA recombination in BMV. Mutations in BMV RNA replication proteins 1a and 2a^{pol} could alter the frequencies and distributions of crossover sites, implying that at least a significant portion of such recombination was a byproduct of RNA replication, as by template switching. These and other results show that RNA recombination is a major force for repairing BMV genomes damaged by the high mutation rates of viral RNA replication and other events, thereby contributing to BMV survival and adaptability. Subsequently, it was further demonstrated that the recruitment of parental RNAs to a shared replication compartment is a limiting step in intermolecular RNA recombination. These results support a model in which BMV genomic RNAs are individually recruited into replication compartments, and intermolecular recombinants arise only in replication compartments receiving multiple viral RNAs.

Properties and Functions of Viral Gene Products

BMV RNA3 encodes two proteins, 3a and CP, that are dispensable for RNA replication but are required for systemic spread (Fig. 1). Disruption of the 3a gene blocks cell-to-cell movement, limiting infection to individual, directly inoculated cells. The 3a protein shares multiple properties with cell-to-cell movement proteins of other viruses, including cooperative binding to single-stranded RNA, localization to the plasmodesmatal connections, and induction of virion-containing tubules from the surface of BMV-infected protoplasts. Disruption of the CP gene stops virus spread to uninoculated leaves. Whether local cell-to-cell spread occurs in the absence of CP depends on several factors including the 3a allele and the host plant.

Protoplast studies showed that BMV RNA replication and sub-genomic RNA4 synthesis require 1a and 2a^{pol} but not 3a or CP. The conserved central domain of 2a^{pol} shows similarity to RdRps encoded by picornaviruses and many other RNA viruses. The N-terminal 1a domain is related to alphavirus protein nsP1 and contains m⁷G methyltransferase and m⁷GMP covalent binding activities required for capping viral RNA *in vivo*. The C-terminal 1a domain has sequence similarity to super-family I NTPase/helicases and NTPase activity that is required for RNA template recruitment and RNA synthesis. The N- and C-proximal domains are separated by a short proline-rich sequence that may serve as a flexible spacer. As shown in several systems, the C-terminus of BMV 1a interacts with the N-terminus of 2a^{pol} and this interaction is required for the recruitment of 2a^{pol} into the viral replication compartments.

BMV 1a and Viral Replication Compartments

In yeast cells replicating BMV RNAs, the outer perinuclear endoplasmic reticulum (ER) membrane is invaginated towards the lumen to form numerous 50–80 nm spherular invaginations, which are referred to as spherules. Similar membrane invaginations are seen in plant cells infected by viruses from *Bromoviridae*, *Tombusviridae*, and *Tymoviridae* families, and in animal cells infected by viruses in and beyond the alphavirus-like super-family. However, in BMV-infected *N. benthamiana* cells, there are three types of polymorphic vesicles that are associated with cytoplasmic ER membranes but are absent from the perinuclear ER region. Type 1 vesicles are ~66 nm in diameter with some spherule-like structures that remain connected to the ER through neck-like structures and as such, type 1 vesicles resemble those formed in yeast cells. Type 2 vesicles are ~359 nm in diameter and likely are induced

by CP. Type 3 vesicles are most probably formed by fusing type 1 and type 2 vesicles. Some possible reasons for the differences in BMV-induced membrane rearrangements between yeast and *N. benthamiana* are likely due to the organization and lipid composition of the ER membranes in yeast and *N. benthamiana* or possible variation in relative protein expression levels and replication efficiency in each system.

Using immunogold-labeling and electron microscopy in yeast, replication proteins 1a, 2a^{pol}, and nascent BMV RNAs were found to be localized to the spherule interiors, which remain connected to the cytoplasm by a narrow neck that likely allows for the import of ribonucleotides required for replication and the export of offspring RNAs (Fig. 2). Immunogold and biochemical studies show that each spherule contains one or a few hundred 1a proteins and ~25-fold fewer 2a^{pol} proteins along with specific host proteins (Fig. 2 and see the Section on “Host Factors in RNA Replication” below). The structure, assembly, and operation of these spherular replication complexes have functional and perhaps evolutionary links to the replicative cores of retrovirus and dsRNA virus virions, which sequester viral RNA replication templates and their polymerases in a protein shell.

BMV 1a serves as the primary organizer to form active replication compartments: it invaginates the outer ER membranes into the ER lumen to form spherules, recruits 2a^{pol} via 1a-2a^{pol} interactions, recruits RNA templates into the interior of preformed spherules by recognizing the *cis*-element RE present only in viral genomic RNAs, and also interacts with and recruits specific host factors to the site of viral replication (Fig. 2, see below in the Section of “Host Factors in RNA Replication”). Spherular invaginations are formed when 1a is expressed in yeast cells in the absence of any other viral proteins or RNA templates. Localization of 1a to the perinuclear ER membrane requires an N-terminal amphipathic α -helix, termed Helix A (amino acids 392–407). NMR analysis shows that three leucine residues are deeply immersed into SDS micelles that mimicked a lipid bilayer. Substitutions of the three leucine residues with alanine prevent 1a from associating with the perinuclear ER membrane, and block spherule formation. In addition, Helix A plays critical roles in regulating the size and frequency of spherules as several individual substitutions in Helix A lead to similar viral replication defects including the formation of spherules that are more numerous in number but smaller in size.

A second amphipathic α -helix, Helix B (amino acids 415–433), plays a crucial role in 1a's function as a viroporin to permeabilize ER membranes to release oxidizing potential, which requires host thiol oxidase Ero1p (ER Oxidation 1), from the ER lumen to promote the formation of disulfide-bound 1a multimers, 1a's RNA capping activity, and active genome replication (See Ero1p in the Section “Host Genes Required for Viral Replication Activity”).

Host Factors in RNA Replication

As for many other viruses, the small size of BMV genome relative to the complexity of BMV replication suggests that many, if not most, steps in BMV RNA replication involve contributions from host factors. Indeed, genetic and systematic genome-wide screens have identified more than 100 genes that, when deleted, inhibited or enhanced BMV RNA replication by at least 3-fold. The mechanisms by which BMV usurps host factors to complete the various steps of its life cycle are illustrated in Fig. 2.

Host Genes That Regulate Lipid Metabolism and Membrane Composition

Since positive-strand RNA viruses replicate on intracellular membranes, cellular lipid synthesis and appropriate lipid composition are crucial for their replication. BMV replication increases total fatty acids per yeast cells by 33%. Mutation or deletion of the *OLE1* (OLEic acid requiring 1) gene, which encodes for the $\Delta 9$ fatty acid desaturase that converts saturated fatty acids to unsaturated fatty acids (UFAs), revealed that BMV RNA replication requires UFA levels five times higher than those required for normal yeast growth. Moreover, the gene products of *DOA4* (Degradation Of Alpha 4), *SPT23* (SuPpressor of Ty 23), and *MGA2* (Multicopy suppressor of GAM 2), which are involved in regulating the expression of lipid metabolism genes, including *OLE1*, are also critical for proper BMV RNA replication.

As major structural constituents of membranes, phospholipids are particularly important for the formation and activation of viral spherules. Phosphatidic acid is a precursor for both phospholipids and storage lipids. phosphatidic acid can be used to make phospholipids for membrane synthesis during active cell growth, or it can be converted to the storage lipid precursor diacylglycerol by Pah1p when cell growth reaches the stationary stage. Deleting *PAH1* led to a 2-fold increase in total phospholipids levels, resulting in twice as many spherules and a 3-fold increase in viral replication. Further studies showed that BMV replication leads to a 25% increase in the levels of phosphatidylcholine, which is predominantly enriched at the sites of BMV replication in both yeast and barley cells. At least in yeast, BMV 1a interacts with and recruits Cho2p (Choline requiring 2), an enzyme involved in the conversion of phosphatidylethanolamine into phosphatidylcholine, to the viral replication sites to promote phosphatidylcholine synthesis, and facilitates BMV replication. In addition, deleting *ACB1* (Acyl-CoA-Binding 1), another gene that regulates general lipid transport and synthesis, reduced BMV replication by up to 30-fold and it led to the formation of smaller but more abundant spherules compared to those in wild-type cells.

Host Genes That Induce/Stabilize Spherules

Host factors are also essential to form and/or maintain BMV-induced spherules. The reticulons are a family of proteins that stabilize highly curved tubules in the peripheral ER. Through an interaction with BMV 1a, the reticulons are relocated from the

peripheral ER into the interior of the spherules. The reticulons were shown to stabilize the membrane curvature in the neck of the spherules and to also regulate the size and number of spherules. Components of the endosomal sorting complex required for transport (ESCRT) are also essential for spherule formation. One group of ESCRT genes regulate BMV RNA replication and the frequency of spherule formation while a second group of genes regulate RNA replication independent of spherule formation. In particular, deleting *SNF7* significantly reduced viral replication and abolished detectable spherule formation. The current model suggests that BMV 1a initiates the invagination of the perinuclear ER, followed by recruitment of Snf7p and other ESCRT components to constrict the wide membrane rim, allowing the formation of the spherule body and neck. The reticulons in turn stabilize the curvature in the neck and regulate the size of the spherules.

Host Genes That Regulate Translation of Viral Proteins and 1a Targeting

Until recently the mechanism by which BMV 1a is targeted to the perinuclear ER was unclear. It was shown that Erv14p (ER-vesicle protein of 14 kDa), a cargo receptor in COPII (COat Protein complex II) coated vesicles, not only interacts with 1a but helps localize it to the perinuclear ER. Deletion of *ERV14* disrupts the proper distribution of 1a and significantly inhibits BMV RNA replication.

Host ribosomes recognize the genomes of positive-strand RNA viruses to initiate translation of the viral proteins. Once sufficient viral replication proteins accumulate, viral genomic RNAs are recruited out of the cellular translational machinery and into spherules to serve as templates for viral replication. For BMV, control of these two functions is tightly regulated by the host complex consisting of Pat1p (Protein associated with topoisomerase 1) and 7 members of the Lsm (Like SM) family: Lsm1p to Lsm7p. Lsm1–7-Pat1 complex binds to the 5' and 3' untranslated regions (UTR) of BMV RNAs to circularize the RNAs to facilitate translation. When BMV 1a is present, 1a binds to the viral RNA and interacts with the Lsm1–7-Pat1 complex, likely disrupting Lsm1–7-Pat1 mediated 3'-5' circularization, thus repressing translation to allow recruitment of the viral RNA to the spherules. Moreover, classical yeast genetic approaches identified *DED1* (Defines Essential Domain 1), an RNA helicase required for translation of all yeast mRNAs, to regulate translation of 2a^{pol} relative to other replication factors.

Host Genes Required for Viral Replication Activity

Host factors are also essential to activate the viral replication proteins after spherules have been assembled. Ydj1p (Yeast dnaJ 1), a J-protein co-chaperone of Hsp70 and Hsp90, is required to activate the BMV RNA replication complexes. In yeast with a mutation in the *YDJ1* gene, negative-strand RNA synthesis is inhibited even though 1a, 2a^{pol}, and RNA3 were recruited to ER membranes. The results suggest that the Ydj1p chaperone likely modulates 2a^{pol} folding or assembly into the complex. BMV RNA replication also depends on the ER luminal thiol oxidase Ero1p. 1a can act as a viroporin by permeabilizing ER membranes to release the Ero1p-generated oxidizing potential from the ER lumen to activate 1a's capping function via a new state of 1a multimerization involving oxidized linkages and potential conformational changes within the protein. 1a mutants lacking the viroporin function were able to recruit and stabilize positive-strand RNA3 templates but did not support significant RNA replication.

Transmission and Host Range

BMV transmission in plants is not well characterized. BMV can be transmitted in the field by human activities involved in agricultural production, such as machinery trampling. In laboratory settings, plants can be easily infected by mechanical inoculation using sap prepared from BMV-infected tissues, purified virions or virion RNAs, or *in vitro* transcripts from cloned viral cDNAs. Vectors transmitting BMV in the field are unknown. Spotted cucumber beetles and nematodes in the genus *Xiphinema* have been reported to be able to transmit BMV in the laboratory.

BMV replicates and encapsidates its RNAs in directly inoculated cells from a wide variety of plants, but has a fairly restricted host range for systemic infection of whole plants beyond monocotyledonous plants. The effective host range for BMV infection thus appears to be determined at the level of initiating or sustaining infection spread from the sites of primary infection.

Exchanging genomic RNAs, individual genes and gene segments among BMV strains and between BMV and other viruses shows that adaptation for infection spread in particular host plants depends not only on 3a and CP but also on features of RNA1 and RNA2. Host adaptation of 3a generally exerts the predominant effects on infection spread, and only a few amino acid changes in 3a are required to extend BMV host range from monocotyledonous to dicotyledonous plants. However, changes modulating the efficiency of systemic spread also map to 1a and 2a^{pol}. Such changes may alter systemic spread through host-specific effects on RNA replication, as by influencing the ability of the virus to replicate and spread faster than host defense responses. Alternatively, 1a and 2a^{pol} may possess additional functions, as for some C-terminal 2a^{pol} sequences that are dispensable for RNA replication but required for efficient systemic infection.

BMV primarily infects monocotyledonous cereal crops such as barley, maize, rice, wheat, and sorghum, as well as model plants *Brachypodium distachyon* and *Setaria viridis*. While *N. benthamiana* is a dicotyledonous host for BMV, *Arabidopsis thaliana* is generally considered as a non-host even though it allows BMV to infect in rare conditions. Screening numerous accessions and mutants of *Arabidopsis*, CPR5 (Constitutive expresser of Pathogenesis-Related genes 5) was identified as a key restriction factor for BMV systemic infection in *Arabidopsis*. Although *Arabidopsis cpr5* mutant plants show an enhanced resistance to multiple bacterial and oomycete

pathogens and several positive-strand RNA viruses compared to wt plants, they all support efficient systemic BMV infection. BMV RNA replication increased at the single-cell level by 6-fold in protoplasts prepared from *cpr5* mutant plants compared to wt. The allowance for BMV replication in various *cpr5* mutants is independent of host defense-related salicylic acid, jasmonic acid, and ethylene. *Arabidopsis* CPR5 is a component of nuclear pore complexes and serves as a selective barrier to restrict nuclear access of signaling cargos. However, the mechanisms whereby *Arabidopsis cpr5* mutants allow BMV to replicate efficiently in single cells and promote systematic infection are unclear. The role of CPR5 might be direct, or it could indirectly regulate specific downstream effectors that might be responsible for the non-host resistance in *Arabidopsis* and possibly other dicotyledonous plants.

BMV Application in Biotechnology

BMV was used to produce the first infectious transcripts from cloned RNA virus cDNA in 1984. Specially designed BMV cDNA clones were transcribed to produce capped *in vitro* transcripts of genomic RNAs 1–3, each with the natural viral RNA 5' end and only a few extra nucleotides at the 3' end. Mixtures of all three BMV RNA transcripts, but not their parent cDNA clones, were infectious to barley plants, a natural BMV host.

This ability to engineer the expression of infectious transcripts provided a means to manipulate the viral RNA genome at the cDNA level using recombinant DNA technology, which has subsequently proved applicable to many other RNA viruses. In one of the first applications of these new reverse genetics approaches, it was successfully demonstrated that foreign genes could be inserted into the viral genome while retaining the ability to replicate and express genes. Using a transcribable BMV RNA3 cDNA clone, the CP gene was replaced with the bacterial reporter gene chloramphenicol acetyltransferase (CAT). When *in vitro* transcribed and inoculated onto barley protoplasts with RNA1 and 2 transcripts, this RNA3 derivative was replicated and produced CAT activity at higher levels than previously achieved by DNA-based transformation. This first demonstration that RNA viruses can be engineered at the cDNA level showed that the viral RNA genome functions in a sufficiently flexible and modular fashion to tolerate even large changes such as whole gene replacements without substantial optimization, which has significant implications for virus evolution, biotechnology research and applications such as additional gene expression vectors.

RNA interference (RNAi) or gene silencing has been widely employed as a powerful tool to reveal gene functions in plants by degrading gene-specific transcripts. Virus-induced gene silencing (VIGS) knocks down gene expression of targeted cellular genes during virus infection, without a need to make transgenic plants. A BMV strain (fescue strain) isolated from tall fescue has been engineered as a VIGS vector by inserting a fragment of the target genes into the 3' UTR of RNA3. These BMV vectors have been successfully used in barley, maize, rice, and sorghum to understand gene function otherwise hard to achieve.

Future Perspectives

Through a variety of intrinsic features and the work of many investigators, research on BMV not only has advanced understanding of bromoviruses, but also has contributed significantly to general virology and molecular biology. Some of the challenges for the future include improved definition and analysis of distinct substeps in viral RNA synthesis including initiation, elongation, termination and capping; better characterization at molecular, cellular and tissue levels of the pathways and mechanisms involved in infection spread and the interplay of virus-directed processes and host defenses; and improved understanding of the linkages between different infection processes including regulated gene expression, RNA replication, encapsidation and spread. Since the mechanism of action has been characterized for several host genes involved in BMV replication, the manipulation of host genes via knockout, knockdown, targeted substitutions, or overexpression could potentially be used as a way to achieve viral control in crop plants.

Glossary

Cross Protection It describes a phenomenon in that an initial infection of a host plant with a mild strain of a virus induces resistance in that plant to the infection of another, closely related virus potentially protecting the plant from disease caused by a more virulent isolate.

Genome Activation Ilarviral genomic RNAs alone are unable to establish infection in plants, unless the coat protein is present. This function of the coat protein is termed genome activation and is specific for ilarviruses and closely related alfamoviruses. The event is triggered by binding of the coat protein RNA binding domain to the 3' terminus of genomic RNA.

RNA Silencing A fundamental, evolutionarily conserved and sequence-specific mechanism that is triggered by double-stranded RNA and regulates gene expression in

eukaryotes. It is a primary antiviral defense mechanism in plants and other living organisms.

RNA Silencing Suppressor A countermeasure to RNA silencing, often a protein encoded by a virus which interrupts a single, or multiple steps in the RNA silencing pathway such as binding to small interfering RNA and thereby preventing their incorporation into the RNA induced silencing complex.

Sub-genomic RNA A segment of RNA generated from a genomic RNA via an internal promoter that has the same 3' end as the genomic RNA, but has a deletion at the 5' end. The sub-genomic RNA makes it possible to efficiently translate the downstream open reading frame of the genomic RNA.

Tripartite Genome A viral genome consisting of three genomic fragments, which are encapsidated into three separate virions.

Introduction

The family *Bromoviridae* contains important genera of plant viruses, with host ranges varying from narrow to very wide, and infecting herbaceous plants, shrubs and even trees. Several of them are responsible for major epidemics in fodder crops such as tomato, cucurbits, bananas, or alfalfa. The members of the family *Bromoviridae* have spherical or bacilliform particles with a tri-segmented, positive-sense, single-stranded RNA (ssRNA) genome, packaged in separate virions. Bromovirids can be transmitted mechanically, via the pollen, seeds or by insect vectors.

As shown in [Tables 1](#) and [2](#), the *Bromoviridae* family includes six genera: *Alfavirus* (one member, type species: *Alfalfa mosaic virus*, AMV), *Anulavirus* (two members, type species: *Pelargonium zonate spot virus*, PZSV), *Bromovirus* (six members, type species: *Brome mosaic virus*, BMV), *Cucumovirus* (four members, type species: *Cucumber mosaic virus*, CMV), *Ilarvirus* (22 members, type species: *Tobacco streak virus*, TSV), and *Oleavirus* (one member, type species: *Olive latent virus 2*, OLV-2). Genus demarcation criteria are based on natural host range, method of transmission, detailed morphology and properties of particles, organization of RNA genome, replication schemes and producing defective RNAs and satellite RNAs.

The two prototype genera, *Bromovirus* and *Cucumovirus*, are the genera mostly related, with the latter being agriculturally important. Both bromo- and cucumoviruses share such properties like the molecular and genetic features of their tripartite RNA genome, the number of encoded proteins and similar virion structure. The computer-assisted comparisons of aa sequences reveal significant similarity among their RNA replication proteins, much beyond the presence of characteristic GDD motif for 2a or for helicase/transferase domains in 1a. More broadly, the replication proteins share aa sequence similarity within the alphavirus-like super-family of positive-strand RNA viruses, which includes numerous plant and important animal/human viruses. The type members of different genera, such as CMV, BMV and

AMV, have and continue to constitute excellent models for molecular research on viral gene expression, RNA replication, virion assembly, RNA recombination, epidemiology or the role of cellular genes in basic virology.

Phylogeny and Biodiversity of the Family *Bromoviridae*

Although RNA1, 2 and 3 overall keep a great similitude in their sequences, clearly rearrangements of RNAs has been done for members of the Bromoviridae. Both RNA recombination but also segment reassortment played a major role as the sources of variation in shaping the bromovirids member groups, being important contributors to the evolutionary history of the family, especially for the genera *Bromovirus*, *Cucumovirus* and *Ilarvirus* (Figs. 1 and 2). However, doubts have been shed on the biological significance of the official taxonomy of the family *Bromoviridae*. To better understand the taxonomy, attempts have been made to reconcile the incongruences observed in the viruses' evolutionary radiation caused by recombination and reassortment. These two processes could create new genetic variability and then these primary variants would undergo further selection for functional genomes of individual viruses. Consequently, the variants generated by reassortment and recombination events must have been initially viable which represents the first selective filter while further directional selection fine tunes the newly created RNAs. RNA segment reassortment was probably common at the origin of the bromoviruses and cucumoviruses as well as at the origin of Alfalfa mosaic virus, American plum line pattern virus and Citrus leaf rugose virus. Furthermore, recombination analyzes done for each of the three genomic RNAs revealed very common crossovers within the members of the genera *Bromovirus*, *Cucumovirus* and *Ilarvirus*, but also mixed recombination involving species from different genera. It seems that bromoviruses and cucumoviruses did split from a common ancestor forming distinct clades due to crossover events in RNA3, whereas protein 2b promoted the selection of a CMV-TAV RNA1/2-RNA3 recombinant. In the 5' untranslated regions (UTR) of CMV RNA3 the sequence rearrangements have likely been the precursors of the radiation of three cucumovirus subgroups. The results illustrated in Fig. 2 confirm a clear separation between the genera *Bromovirus* and *Cucumovirus*, while the ilarviruses constitute their own cluster; two other genera (*Anulavirus* and *Oleavirus*) are more unique within the family. Although these results suggest that AMV should be included in the ilarviruses, its unequivocal assignment has yet to be resolved, especially because AMV differs from other ilarviruses with the mode of transmission, by aphids versus by pollen and thrips. Bromovirids are members of a larger alpha-like supergroup based upon both 1a and 2a proteins whereas 3a proteins cluster the bromovirids together with other viral groups into a separate pool of movement-associated proteins. In general, the constructed phylogenetic network not only reflects the initial genetic exchanges but also confirms the taxonomic status of the different genera within the family *Bromoviridae*, notwithstanding the phylogenetic disturbances caused by genetic exchange.

Virion Properties and Structure

Virions of bromovirids are non-enveloped, being either spherical or pseudo-spherical, with $T = 3$ icosahedral symmetries, and a diameter of 26–35 nm (genera *Anulavirus*, *Bromovirus*, *Cucumovirus* and *Ilarvirus*), whereas genera *Alfavirus* and some ilarviruses have bacilliform virions, of diameters 18–26 nm and lengths of 30–85 nm. In *Oleavirus* virions have different shape.

In genus *Bromovirus* three types of icosahedral particles are composed of 180 molecules of a 20 kDa CP, and encapsidate different RNA components: RNA1 (Mr c. 1.1×10^6), RNA2 (Mr c. 1.0×10^6) and RNA3 plus sgRNA4 (Mr c. 0.75×10^6 and 0.3×10^6). In addition to viral RNAs, BMV virions have been recently reported to package small amounts of host RNAs, with their

functions yet to be determined. The members of the genus *Cucumovirus*, in addition to three genomic RNAs, encapsidate two sub-genomic RNAs (sgRNAs) and a satellite RNA.

The crystal structures of both BMV and CCMV have been resolved showing very similar organization (Fig. 3), with the CP subunits folded into a beta-barrel core organized within the protruding both pentameric and hexameric capsomers. The interactions among hydrophobic aa residues stabilize the capsomers, and the hexameric subunits are further stabilized via interactions between N-terminal portions, where six short beta-strands form a tubule called beta-hexamer. Mutational analysis demonstrated that beta-hexamer was not required for virion formation but rather modulated virus spread *in planta*. In addition, the capsomers

Fig. 1 Phylogenetic trees obtained for the three genomic segments RNA1, RNA2 and RNA3, by concatenating coding and non-coding regions and fitting a heterogeneous nucleotide-substitution model using CODEML. See Table 2 for virus names and abbreviations. The three trees have been aligned with a color-coded system for each genus to show similarities and differences. The trees are reproduced from Codoner, F.M., Elena, S.F., 2008. Fig. 2 Evolution of the family *Bromoviridae*. Unrooted phylogenetic network illustrating the evolutionary history of the family *Bromoviridae*. The different viral species in the family are linked to each other via multiple paths of interconnecting network rather than as single tree, which suggests the effects of recombination and reassortment events. Figure reproduced from Codoner, F.M., Elena, S.F., 2008. The promiscuous evolutionary history of the family *Bromoviridae*. *Journal of General Virology* 89, 1739–1747 with permission (modified by C. Fauquet).

are held together by interactions through C-terminal portions that extend radially from the capsid. The C-termini are anchored between the beta-barrel core and the N-proximal loop, and this interaction might be responsible for initiation of assembly of CCMV capsids. The structure of BMV is organized similarly to that of CCMV such that both capsids undergo well-studied reversible structural transitions where shifting pH from 5.0 to 7.0 causes capsid expansion. However, some CP mutations can further stabilize the capsids. Capsids are also stabilized by metals at multiple binding sites that coordinate the amino acids from adjacent CP subunits.

The packaged RNAs interact with the basic N-terminal aa of the CP in the torus-shaped sub-shell inside the BMV capsid so to neutralize the phosphate groups. Other sites of RNA interaction localize to the internally-proximal basic aa of the CP subunits. The RNA encapsidation signals have been mapped on BMV RNAs, especially to both the 3' UTR and a central sequence in RNA3. The co-packaging of sgRNA4 is contingent upon both RNA replication and translation of CP.

The detailed knowledge of CCMV capsids provided opportunities in nanotechnology, e.g., for the reversible pH-dependent gating, useful during the regulation of size-constrained biomimetic mineralization. The interior surface of CCMV capsids can be engineered of as differentially functionalized CP subunits, to act e.g., as a ferritin surrogate that spatially constrains the formation

of iron oxide nanoparticles. Also, the electrostatically driven adsorption on Si and amine-functionalized Si as well as the fabrication of multilayer CCMV films have been reported. The electrostatically patchy protein cages of CCMV can be used to direct the assembly of super lattices for RNA encapsulation.

Fig. 4 Genome organizations representatives of the six genera of the family *Bromoviridae*: (A) genus *Alfamovirus*, *Bromovirus*, *Ilarvirus* subgroups 3 and 4 and *Oleavirus*. (B) genus *Anulavirus*. (C) genus *Cucumovirus* and *Ilarvirus* subgroups 1 and 2. The 3' termini form either tRNA-like (B) or complex structures (A, C) shown as black square boxes. Figure from Bujarski, J., Gallitelli, D., García-Arenal, F., *et al.*, 2019. ICTV Virus Taxonomy Profile: *Bromoviridae*. Journal of General Virology 100, 1206–1207.

Genome Organization and Expression

The total length of the *Bromoviridae* RNA genome is approximately 8 kb, with three RNA segments capped at the 5' terminus. Whereas the highly conserved within members, the not polyadenylated 3' termini fold into strong secondary structures. These structures are either aminoacylable tRNA-like (genera *Bromovirus* and *Cucumovirus*) or forming other not aminoacylated arrangements (genera *Alfamovirus*, *Anulavirus*, *Ilarvirus* and *Oleavirus*) (Table 1). RNAs 1 and 2 are monocistronic and they code, respectively, for viral replicase proteins 1a and 2a (Fig. 4). Protein 1a has two distinct domains of guanylyl transferase and helicase, and it is involved in anchoring the replicase complex to the endoplasmic reticulum membrane, and induces the formation of membranous vesicular mini-organelles called spherules where RNA replication occurs. In AMV the replicase proteins interact with the tonoplast. Protein 2a is the actual RNA-dependent RNA polymerase enzyme that interacts with protein 1a and synthesizes the vRNAs. Mutations and deletions in 1a/2a ORFs helped to identify the regions active in BMV RNA replication as well as regions responsible for interaction with the cellular membrane or for interactions between 1a/2a polypeptides. An active BMV replicase preparation has been extracted. The anulavirus encodes the smallest RdRp (2a) protein within the family. For cucumoviruses and in some ilarviruses RNA2 is dicistronic encoding a protein 2b, that is part of the C-terminal region of the protein 2a. Protein 2b was found to act as suppressor of RNA interference, being involved in the inhibition of viral gene silencing but also in systemic movement and affecting the symptoms.

RNA3 encodes the movement (MP) and coat (CP) proteins, the latter being translated from the subgenomic (sg)RNA4. BMV CP is a multi-functional protein. In addition to its structural/encapsidation role, it also coordinates the viral infection processes including (1) participation in the formation of replication factories, (2) repression of RNA replication but also translation, and (3) stimulation of BMV RNA accumulation at lower CP levels. Moreover, the BMV CP participates in RNA recombination events; an analogous function to that of BMV CP was assigned to nucleocapsid proteins in retroviruses and coronaviruses. The multiple functions of CP are exercised by effective binding to several distinct sites in RNA3, including the 3' non-coding hairpin, two central regions, and possibly at the 5' end. The contact BMV CP amino acids have been mapped at distinct parts of the CP monomers. Since BMV replicase complex also binds to most of these sites it has been postulated that the CP is involved in the regulation of BMV RNA replication such that the repression of RNA accumulation and translation occurs at higher levels of BMV CP, while stimulation of BMV RNA accumulation at the lower CP levels. While CP is usually translated from the encapsidated 3' sgRNA4, Olive latent virus 2 encapsidates a sgRNA with no apparent messenger activity whereas CP is translated from another non-encapsidated sgRNA4. The purified genomic RNAs are directly infectious but for some bromovirids the presence of CP is necessary (e.g., for AMV or ilarviruses).

The 32 kDa MP of bromovirids has a conserved RNA binding domain that binds to vRNA and assists with viral transport. There are two groups among the members of the family *Bromoviridae* regarding the cell-to-cell transport; those that do not require participation of virions and those that transport whole virions. In the first group only the MP-RNA entity is transported (non-virion transport) in a form of either the complex of MP and vRNA, or a triple complex of vRNA, MP and CP. For the first group, the prototype example is TMV whereas members of the genus *Bromovirus* have a similar mechanism, which has been demonstrated for CCMV. The MP of these viruses belongs to the 30K superfamily of MPs that appear to interact with cellular microtubules. In the second subtype, where the transported complex is vRNA-MP-CP, the typical example is CMV, a comovirus. In this case, the CMV MP exhibits the binding affinity to the actine microfilaments. The second group transports whole virions intercellularly through plasmodesmata inside the microtubules (virion transport). BMV and AMV are the members of two genera that are transported this way. Also for ilarviruses such as PDV or PNRSV, their MPs likely assist during translocation of the entire viral particles alongside the tubular structures. It appears that MPs of these viruses interact with virion CP subunits via a 44C-terminal key aa domain.

For long distance transport, most viruses require the CP which suggests that they are transported in the form of viral particles (virions). This has been demonstrated by showing that bromovirids require unmodified CP and the wild type C-terminus of MP for long distance spread, such as AMV, BMV and CMV. Very likely the CP-MP interactions enhance the systemic transport, independently of the mechanism of short distance (cell-to-cell) transport.

Genomic RNA Replication and Recombination

Replication of bromovirus RNAs are the best studied among the members of the family *Bromoviridae*. Only viral proteins 1a (helicase and methyl-transferase domains) and 2a (RdRp), but not the proteins 3a or CP, are required for RNA synthesis (Fig. 4), first demonstrated for BMV, both in plant and in yeast cells. The cytoplasmic RNA replicase complex localizes to the endoplasmic reticulum membranes called spherules. The extracted bromoviral RdRp preparations have allowed for mapping in vitro on three genomic BMV RNAs the promoter of (–) strand synthesis within the 3' UTR. The promoters of (+) strand synthesis have also been mapped to the 5' proximal non-coding region in BMV RNAs. Likewise, the sub-genomic promoter (sgp) has been localized as a 100 nt subset of the 250 nt intercistronic region in (–) strand in BMV RNA3, being responsible for synthesis (transcription) of sgRNA4. In addition, in the plus strand the 250 nt intercistronic sequence supports other functions including the efficient RNA3 replication, the maintenance of a proper ratio of (+) to (–) strands of RNA3, stabilization of RNA3 via interaction with protein 1a, synthesis (transcription) of sgRNA4, and the assembly of the active RNA replication complex. It also serves as an efficient RNA recombination hot spot. Some bromoviruses as well as togaviruses carry the internal poly(A) tract, as part of the intercistronic region of the RNA3 segment. Besides viral RNA sequences and viral proteins, a variety of essential host genes affecting BMV RNA replication have been identified, by using yeast knockout libraries, as apparently the yeast cells can support a complete replication cycle of this virus Fig. 5.

Both homologous and non-homologous RNA-RNA crossovers has been demonstrated between bromoviral RNAs during infection. Homologous recombination has also been shown during co-infection between two strains of BMV, with some distinct hot spots localized within both the coding and non-coding regions. The role in recombination of proteins 1a and 2a as well as of the CP have been demonstrated in BMV, suggesting the template switching as a likely mechanism for RNA recombination. For the cucumoviruses, the control of recombination frequency resides mainly in the 2a gene.

Members of the genera *Bromovirus* and *Cucumovirus* are capable of producing the defective (d)RNAs and defective-interfering (di)RNAs during infection (Table 1). In particular, strains of Broad bean mottle virus (BBMV) do accumulate RNA2-derived deletion variants after serial passages through broad bean. In BMV, both replicating and non-replicating truncated RNA2-derived artificial diRNAs have been shown to interfere with BMV RNAs in protoplasts. For CMV, several types of RNA3-derived diRNAs have been described.

Biology

The family *Bromoviridae* is one of the most important families of plant RNA viruses, with some members widely distributed in the world. In its entirety, the family has a wide host range (more than 10,000 species) and some members are causing agronomically

Fig. 5 Severe outbreaks of Cucumber mosaic virus (CMV; *Cucumovirus*) containing the necrogenic satRNA (A) and Pelargonium zonate spot virus (PZSV; *Anulavirus*) (B) in crops of canning tomato in southern Italy. Insets show disease symptoms on fruits. Photographs courtesy of ICTV.

important diseases. However, the host range of members of individual genera ranges from significantly narrow (genera *Bromovirus*, *Oleavirus*) to extremely broad (genus *Cucumovirus*). CMV can infect one of the largest number of plant species among plant viruses. Some of these viruses cause major disease epidemics in vegetables, fodder and fruit crops, e.g., in tomato, cucurbits, bananas, or alfalfa, and in fruit trees (ilarviruses). Different virus species are transmitted mechanically, via pollen/thrips, through seeds or by insect vectors like aphids or beetles. It has been speculated that lack of inefficient vectors evolved some bromovirids toward producing larger concentration of viral particles. For CMV, although the virus is prone to recombination, the recombinants are rare during infection, suggesting the presence of strong selection bottlenecks. No direct correlation between virus yield and symptom severity have been observed, but rather the symptoms seem to be associated with changes in specific regions in the RNA genome, as it has been mapped by using the natural strains of BMV, BBMV or CCMV.

Glossary

Bymovirus From barley yellow mosaic virus.

Classification

The bymoviruses are single stranded positive-sense RNA viruses with a bipartite genome in the family *Potyviridae*.

Member Species

The *Bymovirus* genus currently comprises six member species, *Barley mild mosaic virus* (BaMMV), *Barley yellow mosaic virus* (BaYMV), *Oat mosaic virus* (OMV), *Rice necrosis mosaic virus* (RNMV), *Wheat spindle streak mosaic virus* (WSSMV), and *Wheat yellow mosaic virus* (WYMV). The type member of the genus is BaYMV. The currently unclassified *Soybean leaf rugose mosaic virus* seems to be a related virus species, since the C-terminal region of the Nlb gene exhibits about 60% amino acid sequence identity with barley mild mosaic virus and other bymoviruses.

Virion Structure, Serological- and Cytological Properties

Bymoviruses are flexuous filamentous particles of 250–300 nm and 500–600 nm in length and approximately 13 nm in width (Fig. 1(A)). The bipartite, positive-sense RNA genome is encapsidated by a single coat protein (CP). BaYMV is serologically related to WSSMV; WSSMV and WYMV appear to be serologically indistinguishable as neither polyclonal antisera or monoclonal antibodies are able to differentiate between them. OMV and BaMMV are serologically distinct from the other members of the genus. Bymoviruses induce pinwheel-like inclusions and endoplasmic reticulum (ER)-derived inclusions (membranous body, MB) with crystalline lattice-like or tubule dominated morphology (tube-MB) and lamellar structures (lamella-MB) in infected host cells (Fig. 1(B) and (C)). Electron tomography analysis and immuno-gold labeling revealed that both MB types contain viral proteins and components derived from ER membranes. The irregularly arranged lamellar-MB was composed of “rough” ER like structures, whereas regularly arranged tubule-MB was composed of “smooth” ER structures.

Nucleic Acid Properties and Differentiation of Bymoviruses

The bymovirus positive-sense genomic RNAs are approximately 7.5–8.0 kb (RNA1) and 3.5–4.0 kb (RNA2) in length. The RNAs contain the virus-encoded genome-linked viral protein VPg covalently bound to their 5' end and a poly-A tail. The WYMV poly-A tail in naturally infected wheat is variable in length and can even be absent. Recent experiments using *in-vitro* translation and replication showed that polyadenylation of the viral 3' ends impacted translation and negative strand RNA synthesis, indicating that polyadenylation may represent a means for the virus to fine tune translation or replication or may even represent a switch

Fig. 1 Electron microscopy of bymoviruses and infection-derived cellular structures. (A) Transmission electron microscopy of a virus purification from BaMMV infected plants reveals flexuous particles of approximately 250–300 and 500–600 nm in length. between translation and replication of viral proteins. Interestingly, positive effects of cap-independent translation by the 5'UTRs (untranslated region) of WYMV RNA1 and RNA2 was counteracted by the presence of a poly-A tail at the 3'UTR of RNA1 and further increased by the presence of a poly-A tail at the 3'UTR for RNA2. Given that bymovirus resistance is at least in part based on VPg-eIF4 interaction (see below, paragraph on virus control), efficient cap-independent translation by bymoviruses due to a variable polyadenylation status may provide a possibility for the virus for host adaptation.

Sequence similarity comparisons of polyprotein sequences from bymovirus reference numbers published in the 10th ICTV report on the family *Potyviridae* (last revised in October 2018, see "Relevant Websites section") and the genebank reference sequence assembly data for WSSMV (RefSeq assembly: GCF_004117675.1) revealed relationships between polyproteins derived from RNA1 and RNA2 (Fig. 2). For RNA1 polyproteins, WYMV, WSSMV, BaYMV and OMV are more closely related to each other than to RNMV and BaMMV. For RNA2 polyproteins, RNMV and BaMMV form a subgroup, while WYMV, WSSMV, BaYMV and OMV form a different subgroup.

Fig. 3 Genome organization of bymoviruses. Black lines represent viral RNAs with VPg protein bound to the 5' end and variable poly A tail at the 3' end. Square boxes along the RNA represent encoded proteins and their relative localization.

Organization of the Genome and Properties of the Encoded Proteins

Bymovirus RNAs encode for polyproteins, which are proteolytically cleaved into functional proteins. RNA1 contains the typical potyvirus organization of genes except for P1 and HcPro proteins (Fig. 3). Bymovirus RNA2 encodes a P1 protein with amino acid sequence similarity to HcPro, which is restricted to the C-terminal cysteine protease domain of the protein, and a bymovirus-specific P2 protein. As the genome organization for RNA1 is shared among members of the *Potyviridae* family, it is likely that the proteins also have common functions. The large polyprotein derived from RNA1 is proteolytically cleaved into eight mature proteins, P3, 7K, CI (cylindrical inclusion) protein, 14K, VPg (viral protein genome-linked), nuclear inclusion protein a-proteinase (NIa-Pro), nuclear inclusion protein b (Nib), and CP (coat protein). The NIa-Pro is responsible for cleavage. Potyviral CI is thought to be involved in virus movement, VPg is a multifunctional protein involved in translation, replication and possibly movement, Nib is involved in replication, and CP is important for viral encapsidation. Apart from inferring viral protein functions from studies of other potyviruses, the functions of some of the proteins encoded by bymovirus RNAs have been studied in detail for WYMV. The small PIPO open reading frame (ORF) overlapping with the P3 ORF has been predicted in the WYMV genome. Bymovirus RNA2 encodes a polyprotein that is cleaved into the P1 and P2 proteins. The P1 protease cleaves at a site with the consensus sequence (Y,F,G)xG↓(A,N,S). P2 is believed to be important for virus transmission by its vector, *Polymyxa graminis*. VPg proteins are covalently attached to viral genomic RNA and involved in efficient translation of viral RNA. The WYMV VPg protein interacts with the other viral proteins P1 and CP, contains nuclear export and import signals and has been shown to localize to nucleus and cytoplasm during infection, indicating functions of the protein in both cellular compartments. Translocation to the cytosol depends on interaction of VPg with CP, however, the mechanism, by which CP may increase cytosolic accumulation of VPg remains unresolved. The viral VPg interacts with translation initiation factors of the eIF4E family to initiate translation and replication of viral proteins. Recently, WYMV CP has been shown to interact with TaHSP23.6, a wheat small heat shock protein and expression of a range of heat shock proteins was induced upon WYMV infection.

Bymovirus infection causes strong modifications of the ER membrane (membranous body (MB)). The inclusions derived from ER membranes produced during WYMV infection have been shown to contain multiple viral proteins. The integral membrane protein P2 interacts with itself, P1, P3, VPg, NIa-Pro, and CP, rearranges the ER and forms large aggregate structures, thus likely induces the formation of the inclusions by interacting with the ER and recruiting other viral proteins including P1, P3, NIa-Pro, and VPg, but not 7K, CI and CP into these inclusions. Moreover, P2 has been described to recruit host proteins into P2-derived inclusions. P2 interacts with the small GTPase Sar1 important for COPII-vesicle mediated ER-to-Golgi transport in P2-derived inclusions. The formation of the inclusions appears to depend on a functional secretory pathway. As the inclusions are associated with RNA synthesis, they likely represent sites of viral replication. Moreover, P2 appears to be important for transmission of the virus by its vector, *P. graminis*. Upon repeated mechanical inoculation, deletions within the 3' region of the P2 cistron occur for BaYMV, BaMMV and OMV. Two transmembrane domains have been predicted in bymovirus P2, as well as in *Furovirus*, *Pomovirus* and *Benyvirus* CP-Read-through protein (CP-RT). The second of these domains appears to be crucial for vector transmission and is lost in non-transmissible deletion mutants. For C-terminally truncated P2 forms replication still occurs in host cells, indicating that the C-terminal region of P2 is dispensable for virus replication. For BaYMV, the entire P2 protein appears to be dispensable for virus replication, but appears to be important for efficient systemic virus accumulation and symptom development. The peripherally ER membrane-associated WYMV P1 protein interacts with itself and with the other WYMV-encoded proteins, except 14K, and the WYMV integral membrane protein P3 localizes to the ER and Golgi and interacts with itself, P1, P2 and CP. P1 contains cysteine protease activity and believed to cleave the RNA2-derived polyprotein into the mature P1 and P2 proteins. In protoplasts, BaYMV P1 expression increases accumulation of CP, suggesting that P1 enhances RNA1 replication. BaYMV P1 also appears to be essential for systemic infection. Consistent with these functions and in analogy to potyviral P1/HcPro, bymoviral P1 may be involved in the suppression of RNA silencing; however, up to now, there is no experimental evidence for a role of bymoviral P1 as viral silencing suppressor. Nevertheless, that bymovirus double-stranded (ds)RNA replication intermediates are targeted by RNA silencing has been shown. RNA silencing differs between leaves and roots of WYMV infected plants in the way that more small interfering RNAs (siRNAs) – but also more virus- accumulate in roots versus leaves of the plants and that siRNAs in leaf but not root tissues demonstrate a bias towards 5' A or U, and may hence be incorporated into different Argonaute complexes. Moreover, Dicer-like gene expression seems to be differently regulated upon WYMV infection in leaves and in roots.

WYMV 7K was shown to localize to ER membranes when fused to GFP. The WYMV CI protein has been shown in reassortant experiments to determine the pathogenicity of virus infection. Three amino acids in the N-terminal region of CI involved in the change of pathogenicity were identified. As replication in protoplasts remained unchanged between different WYMV pathotypes, it was assumed that the reason for different pathogenicity between WYMV pathotypes is related to CI function in virus movement. Nucleotide sequences of several German WSSMV isolates used for virus resistance trials differ in their 14K protein region from the sequences of isolates found in France, Denmark, and the USA by a nona-nucleotide insertion. At present, it is not clear whether the amino acid changes in these virus isolates lead to biological effects and differences in resistance behavior.

Virus Transmission and Movement

The bymoviruses are transmitted by the soil-borne plasmodiophorid *P. graminis*. Despite challenging for some species of the genus, bymoviruses can also be transmitted mechanically. Transmission takes place after the virus-carrying zoospores of the vector penetrate host root epidermal or root hair cells; however, the detailed mechanism by which the virus crosses the zoosporangial plasmalemma to enter the host cell cytoplasm has not been illuminated. No evidence exists to demonstrate that the virus is able to replicate in its vector. WSSMV CP was detected inside *P. graminis* resting spores. Virus inside resting spores remains infectious over many years. Once transmitted to the host plant, the virus moves systemically. Whether the virus moves cell to cell and systemically as virion or as viral ribonucleoprotein complex in its host plants has not been determined.

Symptoms, Epidemiology and Host Range

Typical symptoms of bymovirus infection constitute of chlorotic mosaic of dark green areas on the younger leaves and chlorotic streaks on leaves (Fig. 4), growth depression, reduced vigor, fewer tillers and reduced grain yield. In the field, winter crops usually develop symptoms in late winter and early spring. Symptomatic plants are usually found in patches in the fields. Barley yellow mosaic disease caused by BaMMV and BaYMV was first reported in Japan in 1940. Since, it has also been detected in China, South Korea, and Europe including Belgium, Bulgaria, France, Germany, Greece, Hungary, Italy, the Netherlands, Poland, Russia, Spain, the UK, and Ukraine. In Japan, at least seven strains of BaYMV and two BaMMV strains are known, while in Europe currently two BaYMV and three BaMMV strains have been described. In China, at least six strains of BaYMV are probably present. Crop loss due to the barley-infecting bymoviruses can reach up to 50% in infected areas. Bymovirus-caused wheat yellow mosaic disease can be due to WSSMV and WYMV infection. WSSMV was first identified 1960 in Canada and ten years later in the USA, where it quickly spread throughout the country. In Europe, WSSMV is present in several countries, among them France, Italy, Germany, and Belgium. WSSMV has also been reported to occur in Africa. Wheat losses due to WSSMV have been reported to range between 20 and 25%. WYMV was first reported in Japan and also occurs in India and China. RNMV was first detected in Japan, and then in India in the late 1970th and causes yellow flecks and streaks on rice leaves. OMV was first reported in 1944 in the USA, where it is widely distributed. It is also present in Europe (England, France, Ireland, and Italy). Yield losses caused by oat mosaic disease of more than 50%, even to complete losses, have been reported. With respect to yield losses, it should be noted here that bymovirus infection often occurs as co-infection with furoviruses and the contributions of each virus species to the disease phenotype and associated crop losses have not been dissected. Thus, it remains unclear whether other virus factors contribute to the losses. Apart from other biotic parameters, also abiotic parameters such as temperature, humidity, soil conditions etc. contribute to the yield loss.

Under natural conditions, BaYMV and BaMMV infect only barley, WSSMV and WYMV wheat, OMV oat and RNMV rice. Interestingly, for RNMV mechanically inoculated onto Ludwigia, Corchorus, and Hibiscus species, growth promotion phenotypes have been described.

Fig. 4 Disease symptoms caused by bymoviruses. (A) Barley field showing patches of plants with barley yellow mosaic disease symptoms. BaYMV (B) and BaMMV (C) leaf mosaic symptoms on winter barley leaves.

Diagnosis

Depending on the cultivated variety and the environmental conditions, the severity of disease symptoms caused by bymovirus infection can vary greatly and normally, virus symptoms disappear with increasing temperatures. The frequent occurrence of mixed infections with other viruses makes a precise diagnosis based on the symptoms very difficult or impossible. Thus, immunoassays such as double-antibody sandwich (DAS)- and triple antibody sandwich (TAS)-ELISA are still most commonly used for practical diagnosis. Commercial test kits are available for all bymoviruses except for RNMV. The detection of virus by electron microscopy can be made specific through the use of immuno-gold labeled antibodies. For the detection and differentiation of the serologically closely related WSSMV and WYMV, a multiplex RT-PCR method was developed. Quantification and improvement of detection sensitivity for WYMV could be achieved by real-time quantitative RT-PCR. In addition, a sensitive reverse transcription loop-mediated isothermal amplification (RT-LAMP) method was developed for detection of WYMV and BaYMV. Reliable detection of BaYMV and BaMMV by real-time PCR has also been reported. Furthermore, a RT-PCR protocol to specifically detect OMV has been developed.

The application of High-Throughput Sequencing (HTS), also known as next-generation sequencing (NGS), has proven very successful also for virus detection of bymoviruses in field samples. In barley, the *rym4* gene confers resistance to BaMMV and the common BaYMV pathotype, BaYMV-1. However, a new virus pathotype designated BaYMV-2, which overcomes the *rym4*-controlled resistance, appeared in several European countries. In order to discriminate between BaYMV-1 and BaYMV-2 by molecular methods a dCAPS (derived Cleaved Amplified Polymorphic Sequences) tool was developed and successfully applied to track the spread of pathotype BaYM-2 in France.

It has been recently shown that deep small (s)RNA sequencing is a universal approach for virome reconstruction and RNAi characterization. This approach was used on dried barley leaves from field surveys. Illumina sequencing of sRNAs from plant samples identified besides BaYMV an endornavirus and, in one plant, a novel strain of Japanese soil-borne wheat mosaic virus (JSBWMV).

Control

Apart from preventive measures by decontamination of machinery and man, the planting of resistant crop varieties presently represents the only efficient means of control for bymovirus infection. Cultural practices remain ineffective due to the robustness of resting spores and soil treatments are ecologically unacceptable. While cereal varieties with resistance to *P. graminis* have not been identified, several crop varieties with resistance to one or more bymoviruses are available.

Against barley yellow mosaic disease caused by BaMMV and BaYMV, 19 *rym* resistance genes are known that are attributed to at least nine loci in the barley genome. 15 of these resistance genes are inherited in a recessive manner and are effective against one or more pathotypes or strains of the same virus or against more than one virus. Some of the resistance genes have been mapped and identified. One encodes for the eukaryotic translation initiation factor 4E (eIF4E). *rym4*, *rym5*, *rym6*, *rym_{Hor4224}*, and *rym_{Hor3298}* resistance based on eIF4E are allelic. Alleles confer resistance against different strains of BaYMV and/or BaMMV. The viral VPg interacts with eIF4 and is presumed to be important for virus translation, replication and movement. The second resistance gene encodes a protein disulfide isomerase like 5-1 (PDIL5-1). To our knowledge, nothing is known about the mechanisms underlying protein disulfide isomerase-based resistance to BaMMV and BaYMV. The monogenic resistances are relatively frequently broken and lead to the emergence of new virus pathotypes. Thus, apart from the identification of novel resistance genes and introduction of these genes into breeding programs, the currently most promising way to achieve durable resistance is by pyramiding resistance genes. In the case of WYMV, there is evidence that resistance is, similar to the barley infecting bymoviruses, eIF4E-mediated. Replication studies of WYMV in barley and wheat protoplasts indicated that expression of wheat eIF4E enabled the replication of WYMV in barley, which is otherwise restricted to wheat. Moreover, approaches in transgenic wheat overexpressing the viral replicase gene in antisense orientation resulted in durable resistance against WYMV. Against WSSMV, the resistant trait in commercial winter wheat varieties encodes a single dominant resistance gene on the long arm of chromosome 2D or is controlled in an additive dominant manner by two loci. WSSMV resistance probably limits virus spread from the roots to the shoots of the plants, as leaves of resistant varieties are readily mechanically infected and lead to systemic distribution of virus. OMV tolerance, in which virus accumulates to high titers but symptoms are mild or absent, has been identified in different *Avena* species and is inherited as a quantitative polygenic trait. Most of the Japanese paddy rice varieties can become infected when grown in soil infested with RNMV. To our knowledge, no resistance genes for RNMV have been identified so far. However, a study using transgenic plants overexpressing a HAP (heme activator protein) transcription factor revealed that the plants displayed a resistance phenotype towards RNMV infection by accumulating lower virus titer and the absence of visible disease symptoms. Moreover, infection induced expression of the transcription factor.

Glossary

Badnavirid Virus belonging to the genus *Badnavirus*, family *Caulimoviridae*.

Badnavirus Virus genus of plant double strand DNA virus encapsidated in bacilliform particles.

Pararetrovirus Reverse transcribing viruses that replicate through an RNA intermediate.

Retrotransposons Are genetic elements that can amplify themselves in a genome and are ubiquitous components of the DNA of many eukaryotic organisms.

RTase/RNaseH Enzymes responsible for the replication of the pararetrovirus group.

Introduction

Cacao swollen shoot disease (CSSD) is caused by Cacao swollen shoot virus (CSSV), member of the genus *Badnavirus*, family *Caulimoviridae*. CSSD can be regarded as the major viral disease on cacao and has been recognized as one of the most important diseases in West Africa limiting cacao production. The disease appeared only after the introduction of cacao in West Africa and is probably the result of a host jump from native reservoir plants. It was highlighted for the first time in Ghana in 1922 but was described and named in 1936, then in Nigeria in 1944, in Ivory Coast in 1946, in Togo in 1949, and in Sierra Leone in 1963. CSSV is naturally transmitted to cacao (*Theobroma cacao*) in a semi-persistent manner by several mealybug species. Extensive research on this emerging disease has been conducted since the 1940s in West African Cacao Research Institute (WACRI- now CRIG for Cacao Research Institute of Ghana) and then in other institutes, in virology, epidemiology, and genetic improvement of cacao tolerance to CSSD. Nevertheless yet, the disease has not been controlled and continues to spread into new areas.

Other viral diseases have been also described on cacao in Trinidad and Tobago and in Sri Lanka but associated with slightly different symptomatologies and have not caused epidemics similar to cacao swollen shoot disease. Complete viral genomes have been obtained recently from those diseases and correspond to clearly different badnavirid species: *Cacao yellow vein-banding virus* (CYVBV) and *Cacao mild mosaic virus* (CMMV) infecting cacao in Trinidad, *Cacao bacilliform Sri-Lanka virus* (CBSLV) infecting cacao in Sri Lanka.

Taxonomy

The genus *Badnavirus*, one of the eight genera of the family *Caulimoviridae*, are double stranded DNA (dsDNA) viruses with bacilliform particles that emerge mainly on tropical plants. The most commonly encountered on crops in addition to CSSV on cocoa are Banana streak viruses -BSV- on banana, Dioscorea bacilliform viruses -DBV- on yam and *Citrus yellow mosaic virus* -CIYMV- on citrus. The viruses member of this genus have an extremely wide host range: some viruses are found in many ornamental plants such as *Yucca*, *Dracaena*, *Kalanchoe*, *Hibiscus*, *Pelargonium*, *Bougainvillea*, *Cycas*, *Canna*, *Jasminum*, *Wisteria* and *Commelina* as well as in a significant number of cultivated plants, such as pineapple, fig, sweet potato, grapevine, black pepper, jujube, currant, raspberry, ginger, mulberry, and blackberry-ripe in addition to the major crops mentioned above (Banana, cocoa, and citrus). New badnavirids are regularly identified on new plant species such as *Sophora* from Japan, Yacon, birch, or Aralia Ming (*Polyscias fruticosa* L.) are found hosting badnaviruses. A total of 57 species are currently recognized by ICTV (Table 1) and many more are unassigned species in the genus (> 50). The description of some of these new viruses is certainly linked to the improvement of virus detection and testing techniques, rather than viruses a particular health problem for plant. It should be noted that the species demarcation of 80% identity of sequences has been set more than 15 years ago, and now that so many badnavirid sequences are available, this demarcation threshold should be revisited. It is remarkable that BSV, DBV, CSSV and even RTBV (*Tungrovirus*, *Caulimoviridae*) seem to have many species for a single disease in each case, or would it be possible that in the case of badnaviruses, or even caulimoviruses, that the species threshold might be much lower than 80%?

Host Range and Symptomatology

Experimental host range is limited to species of the large botanical family of Malvaceae but the principal host of the virus is *Theobroma cacao*. Symptoms on cacao trees are mostly seen in leaves, but stem and root swellings, as well as pod deformation also occur. In some

Fig. 1 (A) Symptoms of red-vein banding observed on young flush leaves of cocoa tree in Togo, Klotó area. (B) Symptoms of swellings on chupons of cocoa tree, in Togo, Litimé area. (C) Symptoms of swollen shoot observed on *Theobroma cacao* plantlets four months after agro-inoculation with the Togolese Agou 1 isolate. From left to right: a plantlet inoculated with the wild strain *Agrobacterium tumefaciens* LBA4404 and two plantlets inoculated with the recombinant *A. tumefaciens* bacteria LBA4404 (pAL4404, pBCPX2) containing CSSV insert.

varieties of cacao, particularly Amelonado cacao, reddening of primary veins and veinlets in flush leaves is characteristic (Fig. 1(A)). This red vein banding later disappears. There can be various symptoms on mature leaves, depending on the cacao variety and virus strain. These symptoms can include: yellow clearing along main veins; tiny pin-point flecks to larger spots; diffused flecking; blotches or streaks. Chlorotic vein flecking or banding is common and may extend along larger veins to give angular flecks.

Stem swellings may develop at the nodes, internodes, or shoot tips. These may be on the chupons, fans, or branches (Fig. 1(B)). Many strains of CSSV also induce root swellings. Stem swellings result from the abnormal proliferation of xylem, phloem, and cortical cells. Infected trees may suffer from partial defoliation initially due to the incompletely systemic nature of the infection. Ultimately, in highly susceptible varieties, severe defoliation and dieback occurs. Smaller, rounded to almost spherical pods may be found on trees infected with severe strains. Occasional green mottling of these pods is seen and their surface may be smoother than the surface of healthy pods.

Various isolates were described in Ghana as in Togo with a variability and a gradation in the type of symptoms observed. Severe strains of this virus can kill susceptible cacao trees within 2–3 years. They affect Amelonado cacao, widely considered to give the best-quality cacao, more seriously than Upper Amazon cacao and hybrids which have been selected for resistance to the virus. A few avirulent strains occur in limited, widely scattered outbreaks, usually inducing stem swellings only, and having little effect, if any, on growth or yield. As for other perennial crops, we observe a latency period between the time of infection and the time of symptom expression, which complicates control measures. Moreover, there are periods of remission during which symptoms are not visible.

The natural host range of the virus includes *Ceiba pentandra*, *Cola chlamydanthra*, *Cola gigantea* var. *glabrescens*, *Sterculia tragacantha*, and *Adansonia digitata* with associated symptoms of transient leaf chlorosis or conspicuous leaf chlorosis. Viral sequences belonging to different species have been detected in *C. pentandra* as well as in *Commelina* sp.

Transmission

Fourteen species of mealybugs (*Pseudococcidae* spp.), including *Planococcoides njalensis*, *Planococcus citri*, *Planococcus kenyae*, *Phenacoccus hargreavesi*, *Planococcus* sp. *Celtis*, *Pseudococcus concavocerrari*, *Ferrisia virgata*, *Pseudococcus longispinus*, *Delococcus tafoensis*, and *Paraputo anomalus*, have been reported to transmit CSSV. Only the nymphs of the first, second, and third larval stages and the adult females are able to transmit the virus. The virus does not multiply in the vector and is not transmitted to its progeny. CSSV is transmitted neither by seed nor by pollen. CSSV can infect cacao at any stage of plant growth. The virus is transmitted experimentally to susceptible species by grafting, particle bombardment, by agro-inoculation using transformed

Agrobacterium tumefaciens and with difficulty by mechanical inoculation. Seedlings usually produce acute red vein banding within 20–30 days and, 8–16 weeks later, swellings on shoots and tap roots (**Fig. 1(C)**).

The indigenous species are more difficult to infect than cacao, and mealybugs do not become infective as readily when feeding on them as when feeding on infected cacao.

Virion Structure

It was not until 1940 that through experimentation, the causative organism of the CSSD was identified to be a virus named CSSV. CSSV possesses small non-enveloped bacilliform particles and a double-stranded DNA genome (**Fig. 2**). The bacilliform particles measure $130 \text{ nm} \times 28 \text{ nm}$ in size and have been shown by dot-blot hybridization to occur in the cytoplasm of phloem companion and xylem parenchyma cells.

Genome Organization

Molecular characterization of CSSV had a boost in 1990, thanks to the improvement of the techniques of purification. The first complete genome of a CSSV isolate (Agou1 from Togo) was determined in 1993. Five putative open reading frames (ORFs) are located for this isolate on the plus strand of the 7.16 kbp CSSV genome (**Fig. 3**). ORF1 encodes a 16.7 kDa protein whose function is not yet determined. The ORF2 product is a 14.4 kDa nucleic acid-binding protein. ORF3 codes for a polyprotein of 211 kDa which contains, from its amino- to carboxyl-terminus, consensus sequences for a cell-to-cell movement protein, an RNA binding domain of the coat protein, an aspartyl proteinase, a reverse transcriptase (RTase), and an RNase H. The last two ORFs X (13 kDa) and Y (14 kDa) overlap ORF3 and encode proteins of unknown functions. More than 30 complete viral genomes have since been obtained by different technologies such as Sanger sequencing of PCR amplified full genome and Illumina sequencing. Their size varies from 6.8 kbp to 7.4 kbp. ORFY has been identified in all other complete genomes sequenced. ORFs 1, 2 and 3 are characteristic of all badnavirids unlike additional ORFs which are present only for some badnaviruses (CSSV, Citrus yellow mosaic virus –CiYMV-, Taro bacilliform virus –TaBV).

Phylogeny

Badnaviruses are highly variable at both the genomic and serological level, a feature which complicates the development of both molecular and antibody-based diagnostic tests. Moreover, CSSV isolates were for a long time classified according to the variability of the symptoms expressed on *T. cacao*, but it is not known if there is a correspondence between this variability of symptoms and the intrinsic molecular variability of the viruses.

A first study analyzed the molecular variability of the area of the ORF3 coding for N-terminal coat protein (CP) for 1A-like isolates from Ghana. Successive studies have analyzed molecular variability of CSSV isolates from Togo, Ghana and Côte d'Ivoire in the first part of ORF3 coding for the cell to cell movement protein. These analyses showed a high variability of CSSV isolates and permitted to define several groups (A to P) of sequences (**Fig. 4**). Groups Q, R and T were never detected with these primers. Recently the analysis of all complete viral genomes of isolates from those countries made it possible to describe more exhaustively the variability of this virus and to show that the disease is caused by a complex of many viral

Fig. 3 Organization of the circular genome of the CSSV species. Gray arrows indicate the deduced ORFs 1–3, X and Y capable of encoding proteins larger than 9 kDa. In the ORF3, we indicate the position of the movement protein (MP); coat protein (CP); the RTase/RNaseH region, with the domains for Aspartyl Proteinase (AP); Reverse Transcriptase (RT); and Ribonuclease H (RNase H).

species. Results on phylogenetic relationships between the first Ghanaian and Togolese full sequences showed that these relationships were more influenced by their geographical origin than on whether the sequences originated from mild or severe isolates.

Table 2 shows the nt sequence identity of pairwise combinations of representative CSSV isolates of each molecular group in the RT/RNase H region of ORF3 (500 bp). Considering the 20% divergence threshold in the RTase/RNaseH region indicated by ICTV in a region of 1500 nt for the determination of new badnavirid species, we could define 8 species. Seven species are now recognized by ICTV: *Cacao swollen shoot Togo B virus* (CSSTBV, first described as CSSV, first isolate sequenced, Agou1), *Cacao swollen shoot Togo A virus* (CSSTAV), *Cacao swollen shoot CD virus* (CSSCDV), *Cacao swollen shoot CE virus* (CSSCEV), *Cacao swollen shoot Ghana M virus* (CSSGMV), *Cacao swollen shoot Ghana N virus* (CSSGNV), *Cacao swollen shoot Ghana Q virus* (CSSGQV). Another full genome has been obtained recently and potentially corresponding to the eighth species *Cacao swollen shoot Ghana T virus* (CSSGTV).

Recently a phylogenetic tree was built from all the available complete sequences of badnaviruses (**Fig. 5, Table 3**). It shows that the group of viral species associated with the cacao swollen shoot disease is polyphyletic since the MBV1, HiBV and CiYMV species are positioned at the junction between the two phyla of CSSV species TA, TB (groups B and C), CD, CE (groups E, F, G, H, J, K, L, P) GM and GN on the one hand and GQ (groups Q and groups Q and R) and GT on the other hand.

As has been observed for most viruses studied, that badnavirus populations contain recombinant viruses. This was illustrated for the first time for CSSV with the sequencing of isolate Wobe12 (type member of species CSSTAV). Wobe12 possesses an ORF1 close to ORF1 (96% nt identity) of isolate Agou1 (group C of species CSSTBV) but shares only 75% nt identity with the complete sequence of Agou1. Recombinations allow the emergence of new viral isolates and increases the variability of viral populations beyond what is observed by studying a single region of the genome. The sites of recombination in the genome and their frequency should be extensively investigated in the future to have a better understanding of virus evolution in epidemics.

Epidemiology: Geographical Distribution of Viral Molecular Diversity

Epidemiological characteristics of the disease derive directly from its natural transmission properties. The mealybug vectors (nymph of both sexes and adult females) spread the disease radially over short distances around the periphery of outbreaks by crawling through the canopy from infected trees to adjacent healthy trees. New outbreaks were shown to be occasioned by “jump spread” over greater distances by wind borne viruliferous mealybugs and mainly by the very active small first instar nymphs.

A systematic molecular characterization of viral isolates make it possible to study the molecular epidemiology of CSSV. Viral molecular diversity studied in the first region of the ORF3 for isolates from the three countries: Togo, Côte d’Ivoire and Ghana

Fig. 4 Maximum likelihood phylogenetic tree of CSSV sequences based on alignment of the 5' end of open reading frame 3 (ORF3). Numbers on the branches represent the SH-aLRT (approximate likelihood ratio test) branch supports over 0.7. The names of the CSSV groups A, B, C, D, E, F, G, H, J, K, L, M, N and P are indicated, as well as the names of the corresponding species. The Citrus yellow mosaic virus sequence – CiYMV (AF347695) – is used as the outgroup. The names of sequences include the abbreviation of the country: CI for Côte d'Ivoire, G or Gha for Ghana, To for Togo, a sampling number along with a region code or a number corresponding to the clone number in brackets, and the year of sampling 1993–2016 coded as 93–16. When sequences belonging to different groups are obtained for the same isolate, the letter corresponding to the group is affixed to the name of the isolate.

has provided a picture of the geographical distribution of this diversity in these countries (Fig. 6). In most cases, sequences from the same farm/plot always belonged to the same group, but there were some instances where isolates belonging to two different groups were identified on the same plot/farm. The geographical distribution of the viral molecular diversity shows that some group (species TA or CD, or group C of species TB) have remained well localized in a single country or at the border between two countries, while other species (group B of species TB) have a more ubiquitous distribution in the different regions of the three countries. The ubiquitous nature of the B group may mean it is readily transmitted by mealybugs, probably because of higher concentrations in the cacao phloem than the other groups. This group from species TB tends to induce more easily the typical red vein banding symptom seen in young or flush leaves of infected cacao plants, since most of the samples collected in the Eastern Region containing only this group, whether young or mature, had the conspicuous red vein banding or vein clearing symptom.

When CSSV groups identified in Ghana are compared to those found in Côte d'Ivoire, only species TB and CE are common to both countries. In addition to these two species, Côte d'Ivoire has a species (CD) which have not been detected in Ghana up to now and Ghana also has species TA, GM, GN, GQ, group C (species TB) and groups G, J, K, L (species CE) which have not been identified or detected in Côte d'Ivoire yet. This distribution may reflect differences in cacao crop planting dates in the regions of these countries. These observations make it difficult to predict a single origin for CSSV in West Africa amongst the cacao growing neighboring countries and we can therefore make the assumption that the different putative CSSV species emerged from different sources at different times. In fact, the high variability observed within CSSV populations compared to its very short evolutionary history on cacao trees further suggests the existence of several parallel emergences, more likely by host shift from different native hosts to cacao trees in the various countries of West Africa. Studies on CSSV more exhaustively in adventitious plants or insect vectors would make it possible to better understand the geographical distribution and the epidemiologic factors that lead to the rapid expansion of the disease in some plots. However, the exact role played by these wild hosts in the epidemiology of CSSV is today difficult to investigate, because the prevalence of CSSD is greater in cacao trees than in these alternative host plants.

The diversity of CSSV observed in the CRIG Museum (a collection of viral isolates collected in Ghana since the 1940s) compared to cacao farms in Ghana is interesting from a historical point of view, because this range can be seen as a picture of the diversity of the CSSV population at the time the Museum was established. Indeed, it should be noted that this viral collection has not been regularly updated. The species CSSGQV, CSSGTV currently only detected in the CRIG Museum may have been present previously in cacao farms but were absent or only present at a frequency that avoided detection in the farms. Conversely, groups of the species CE (J, K and L) and group C only detected in cacao farms of the species TB appear to correspond to recently emerged groups in the cacao farms. Group C has been detected in Togo since 1993 but could have emerged either in Togo or in Ghana, since the establishment of the CRIG Museum. Species CE, is underrepresented in the CRIG Museum but present in a high proportion in field samples (29% of the total isolates characterized in Ghana) and appears to correspond to a species that has recently spread to cacao plots especially in the Western and Brong Ahafo regions of Ghana.

The complexity of the molecular diversity of viral species found in symptomatic cacao leaves means that there is a need to study the range of aggressiveness of the different species or groups. In future the symptomatology/aggressiveness associated with single strain infections arising from representative species should be explored as should the impact on hosts from mixed infections of these genomes.

Fig. 5 Maximum likelihood phylogenetic tree generated by PhyML based on complete nucleotide sequences of badnaviruses. The blue sequences correspond to the viral sequences infecting the cocoa tree and associated with the cacao swollen shoot disease. Numbers on the branches represent the SH-aLRT (approximate likelihood ratio test) branch supports over 0.7. The scale bar represents the substitution number per base. The GenBank accession numbers of Badnavirus sequences used are listed in [Table 1](#) and the CSSV sequences are listed in [Table 3](#). Rice tungro bacilliform virus (RTBV-Phi – X57924) was used as outgroup.

Diagnosis

Serological Diagnostics

The virus is not strongly immunogenic; however, several antisera have been raised and shown to react with CSSV. Enzyme-linked immunosorbent assay (ELISA) has been used to detect CSSV but high background values were obtained and difficulties were found in detecting CSSV in plants suspected of having only a low virus titer. Immunosorbent electron microscopy has been used for detection and comparison of some isolates of CSSV in Ghana. Both of these techniques cannot detect latent infection.

**Fig. 6** Geographical distribution of the species complex associated with cacao swollen shoot disease in the different outbreaks in West Africa, (Côte d'Ivoire, Ghana and Togo).

The viro-bacterial agglutination (VBA) test has been found to be a useful test for detecting CSSV in leaf tissue from infected trees. Using this assay, CSSV can be detected in trees showing symptoms as well as in infected, but symptomless, trees. The immunocapture polymerase chain reaction (IC-PCR) technique was adapted to the only detection of CSSV-1A isolates from Ghana (CSSTBV species).

There is considerable strain variation among the many recognized CSSV isolates, some of which react only weakly with certain antisera. Using monoclonal antibodies, four serotypes of CSSV have been distinguished by ELISA analysis of 31 samples of the virus from different geographical locations in Ghana. The efficiency of serological diagnosis depends on the use of polyvalent antiserum able to detect all serotypes. Since the 2000s and the first results on viral molecular variability, no work has been published on the development of serological methods for CSSV but these methods should not be excluded for the implementation of a versatile and sensitive diagnosis.

PCR Diagnosis

For a reliable PCR diagnosis, it is necessary to design primers from conserved regions of the genome. Until 2000, only few badnaviruses were completely sequenced, and only the end of the ORF3, which contains the conserved motifs specific of RTase and RNaseH made it possible to obtain primers useful for diagnosis. After alignment of the first six full-length sequences of CSSV, polyvalent primers pairs were designed in two different parts of the genome, in the movement protein (MP, first part of ORF3) and in the RTase/RNaseH region (third part of ORF3) (Fig. 3) and were then improved to be able to detect new species that were subsequently identified. However, the presence in cacao genomes of retrotransposons containing also the motifs specific of RTase and RNaseH makes it difficult to develop specific CSSV primers in this area.

PCR-based diagnosis is able to detect CSSV not only in symptomless leaves of symptomatic plants, but also in symptomless plants as early as one week post-inoculation. As the sensitivity of diagnosis is better when young symptomatic host plant leaves are tested, it is recommended that validation of the diagnostic test is done using this type of material in the first instance, especially when testing isolates from new areas.

Given the heterogeneous distribution of the virus in the plant, especially in adult trees, this PCR diagnosis should be used primarily to check for infection of plants with suspicious symptoms, or of grafts or rootstocks.

Control of the Disease

Attempts at CSSV control in Ghana have required substantial financial and manpower inputs. The “cutting-out” policies in place in Ghana since the early 1940s which attempted to control cacao swollen shoot disease resulted in the removal of over 190 million trees up to 1988. Over ten million infected trees which still required ‘cutting out’ were identified in the field by 1990.

Control of the swollen shoot disease based only on ‘cutting-out’ campaigns has not been successful due to several factors including political and socioeconomic problems. The better strategy for dealing with the disease is to develop a combination of control measures in an integrated approach. Moreover, this approach should implicate cacao farmers as much as possible.

Mild strain protection is a possibility which is being investigated. Mild strains which appear to confer some protection against the severe strains from species CSSTBV are available and are being tested in the field in Ghana. However, only a closely related mild strain is able to protect against another strain, as has been demonstrated for the Citrus tristeza virus. Now that there are so many different CSSV species, it would seem that it would be impossible to protect the cacao trees against them all.

The control of insect vectors such as mealybugs is difficult to implement due to the excessive cost of the molecules to be used and their toxicity which results to residues in the cacao beans produced by treated trees.

The most effective replantation method is to clear whole areas and replant in large compact block because of the relatively small proportion of trees in the vulnerable peripheral areas. The possibility of isolating new cacao plantings from infected cacao by an isolation distance of 10 m or planting barriers with CSSV-immune crops should be considered. Barrier crops such as banana, plantain, oil palm, coffee, cola, and citrus can form a barrier to the movement of vectors. The ‘cutting out’ of the adventitious plants of the genus *Commelina* recognized as alternative hosts should also be done.

The use of resistant cacao is advocated for replantation as many of the new hybrids available in West Africa do have some partial resistance to CSSV. Replanting with resistant cacao trees, however, requires the installation of a protocol of effective screening for resistance. Severe isolates representative of the different molecular groups should be used as well as a suitable screening method. However, a standardized inoculation method is not yet available because particle bombardment is difficult to develop on a large scale and agro-inoculation needs biosafety confinement. Mealybug transmission tests can nevertheless be set up by the national research institutes of the different producing countries, taking all precautions in terms of confinement (insect proof greenhouses).

Intermediate quarantine facilities are at present hampered by the lack of suitable indexing methods for the virus particularly if the germplasm is to be moved as stem cuttings. New polyvalent PCR diagnosis could be easily tested in intermediate quarantine facilities and compared with the grafting procedure used for indexation on Amelonado cacao seedlings.

Glossary

Defective interfering RNAs RNAs derived from the RNA genome of a virus in which a critical portion of such genome has been lost usually due to defective replication. These RNAs are associated to and depend on the parent virus for infection as it provides the lost factor.

Leaky-scanning Phenomenon in which a weak initiation codon triplet on mRNA is sometimes skipped by ribosome in translation initiation. The 40S ribosomal subunit continues scanning to further initiation codon. The weak initiation codon can be an AUG in a weak Kozak consensus context or a non-AUG codon.

Readthrough Consists of the “translation” of a stop codon, such that the synthesis of a larger proteins is allowed. It is a common phenomenon in viruses, and it has a regulatory function.

RNA silencing A mechanism of transcriptional and post-transcriptional gene regulation operating in many

eukaryotic organisms. It is mediated by 20–25 nt small RNAs produced from various RNA sources and functions in regulating RNA stability and translation as well as in chromatin modification underlying numerous developmental processes. It also plays a significant role in microbe–host interaction.

Satellite RNA A subviral RNA that depends on the co-infection of a host cell with a helper virus for its replication.

Silencing suppressor Virally encoded proteins from diverse families that interfere with host production or effectiveness of small RNAs involved in RNA silencing.

Sub-genomic RNA Viral RNA that derives from and is usually 3′ co-terminal to the viral genomic RNA and that is produced during infection to serve as mRNA for translation of internal and 3′-proximal genes.

Tombusvirid Member of family *Tombusviridae*.

Introduction

In 1988, a series of viruses forming polyhedral virions which enclosed monopartite single-stranded (ss) RNA genomes of ~4 kb and that were represented by Carnation mottle virus (CarMV) were described. Since then, more than twenty-five related viruses sharing significant sequence homology and overall gene arrangement have been identified and are currently known under the generic name of carmo-like viruses. Investigations in the last years have significantly improved our knowledge on the biological and molecular properties of carmo-like viruses which, moreover, has helped to refine their classification. In this article, summary and updated information on this group of infectious agents is provided.

Taxonomy, Classification, and Evolutionary Relationships

The International Committee for Taxonomy of Viruses (ICTV) currently recognizes sixteen genera within the family *Tombusviridae* which, in turn, are clustered into three subfamilies: *Calvusvirinae*, *Procedovirinae*, and *Regressovirinae*. Four out of the fourteen genera included in *Procedovirinae* comprise carmo-like viruses: *Alphacarmovirus*, *Betacarmovirus*, *Gammacarmovirus*, and *Pelarspovirus*. These genera show differential branching in phylogenetic trees based on their encoded RNA-dependent RNA polymerases (RdRps) (Fig. 1). The generic name “carmo” is derived from the first member of the group to be described, CarMV, currently being the type species of the genus *Alphacarmovirus*. Members of each of the four genera share recognizable, yet variable, sequence similarity with members of other genera of carmo-like viruses as well as with other genera of the family *Tombusviridae*. As other components of the

Fig. 1 Phylogenetic tree of the RdRps of tombusvirids. The alignment of was made using MUSCLE while tree was generated with the Maximum Likelihood (ML) algorithm in MEGA7 (<https://www.megasoftware.net/>). The analysis involved 64 amino acid sequences (those corresponding to the RdRps of all recognized tombusvirids). Condensed triangles mark monophyletic lineages. *Tombusviridae* subfamily names are on the right, and members of the four carmo-like virus genera are colored in red (*Alphacarmovirus*), green (*Pelarspovirus*), blue (*Betacarmovirus*), and purple (*Gammacarmovirus*). Virus names and acronyms are as follows: *Angelonia flower break virus* (AnFBV), *Calibrachoa mottle virus* (CbMV), *Cardamine chlorotic fleck virus* (CCFV), *Carnation mottle virus* (CarMV), *Clematis chlorotic mottle virus* (CICMV), *Cowpea mottle virus* (CPMoV), *Cucumber Bulgarian latent virus* (CBLV), *Cymbidium ringspot virus* (CyRSV), *Elderberry latent virus* (ELV), *Furcraea necrotic streak virus* (FNSV), *Galinsoga mosaic virus* (GaMV), *Hibiscus chlorotic ringspot virus* (HCRSV), *Honeysuckle ringspot virus* (HnRSV), *Japanese iris necrotic ring virus* (JINRV), *Maize chlorotic mottle virus* (MCMV), *Maize necrotic streak virus* (MNeSV), *Melon necrotic spot virus* (MNSV), *Nootka lupine vein clearing virus* (NLVCV), *Oat chlorotic stunt virus* (OCSV), *Pea stem necrosis virus* (PSNV), *Pelargonium chlorotic ring pattern virus* (PCRPV), *Pelargonium flower break virus* (PFBV), *Pelargonium line pattern virus* (PLPV), *Pelargonium ringspot virus* (PeIRSV), *Rosa rugosa leaf distortion virus* (RrLDV), *Saguaro cactus virus* (SCV), *Soybean yellow mottle mosaic virus* (SYMMV), *Trailing lespedeza virus 1* (TLV1), and *Turnip crinkle virus* (TCV). *Hepatitis C virus* (HCV) RdRp was used as outgroup.

family, carmo-like viruses have icosahedral virions of about 30 nm in diameter, with $T=3$ symmetry, that is composed of 180 coat protein (CP) subunits of about 37–42 kDa and a ssRNA genome ranging in size from 3.9 to 4.3 kb. In all cases, the genome consists of a unique positive (+) sense ssRNA molecule that contains, at least, five definitive open reading frames (ORFs). Genome organizations of *Alphacarmovirus*, *Betacarmovirus*, and *Gammacarmovirus* are very similar and can be exemplified by those of their type species, corresponding to CarMV, Turnip crinkle virus (TCV), and Melon necrotic spot virus (MNSV), respectively (Fig. 2). TCV is probably the best studied virus among carmo-like viruses. It was the first carmo-like virus for which infectious transcripts were produced from a cDNA clone of the genome and detailed information about genome functions and virion configuration has been obtained, in the latter case including crystal structure determination. TCV genome harbors five ORFs encoding proteins of about 28, 88, 8, 9, and 38 kDa from the 5'- to the 3' end, respectively (Fig. 2). Leaving aside some specific features that will be mentioned in the next sections, the genome organization of pelarspoviruses resemble those of other carmo-like viruses and can be illustrated by the one from its type species, *Pelargonium line pattern virus* (PLPV). PLPV genome contains five genes encoding proteins of about 27, 87, 7, 9.7, and 37 kDa from the 5'- to the 3' end, respectively (Fig. 2). Some carmo-like viruses, such as *Hibiscus chlorotic ringspot virus* (HCRSV, genus *Betacarmovirus*), have additional ORFs whose functions are not entirely clear.

To date, the nucleotide sequences of the 21 definitive carmo-like viruses have been determined (Table 1). These sequenced viruses share similar morphological and physicochemical properties with five additional viruses listed in Table 1, that are recognized as unassigned species of the family *Tombusviridae* by the ICTV. Moreover, genome sequences of four of these viruses have not yet been determined. Most carmo-like viruses are sufficiently distant from each other that they do not cross-react in standard RNA hybridization or serological tests.

Carmo-like viruses have properties in common with viruses belonging to other genera of the family *Tombusviridae*. Their particle structure and CP sequences are closely related to tombus-, aureus-, diantho-, macana-, gallanti-, and avenaviruses. Their RdRp genes share a remarkable level of homology with other tombusvirids and particularly with those belonging to subfamily *Procedovirinae*: *Machlomovirus*, *Panicovirus*, *Alphanecrovirus*, *Betanecrovirus*, *Aureusvirus*, *Gallantivirus*, *Macanavirus*, *Avenavirus*, *Zeavirus*, and *Tombusvirus*. RdRp genes of carmo-like viruses and of other tombusvirids also share similarity with more distantly related viruses, such as luteoviruses. These latter viruses currently belong to family *Luteoviridae* though their reassignment to the family *Tombusviridae* is expected in the near future. In a broader context, phylogenetic comparisons of viral RNA polymerase

Fig. 2 Genome organizations of species of genera *Alphacarmovirus*, *Betacarmovirus*, *Gammacarmovirus*, and *Pelarspovirus* exemplified, respectively, by those of their type species, *Carnation mottle virus* (CarMV), *Turnip crinkle virus* (TCV) and *Melon necrotic spot virus* (MNSV), and *Pelargonium line pattern virus* (PLPV). The colored boxes represent open reading frames with the sizes of the encoded proteins, in kilodaltons, indicated within the boxes. Blue, yellow and pink boxes have been used, respectively, for genes encoding proteins involved in replication, movement and encapsidation/suppression of RNA silencing, as indicated in the inset at the right. The two proteins required for replication are translated from the genomic RNA (gRNA) with the viral RNA-dependent-RNA polymerase (86–89 kDa in the Figure) being translated by readthrough (RT) of an amber codon at the end of the 5'-proximal gene. Thin lines under genomes indicate sub-genomic RNAs (sgRNAs) produced by members of each genera to translate internal and 3' proximal genes. Dashed line of PLPV MP2 marks a noncanonical start codon. The bottom panel at the right corresponds to Northern blot results for detection of viral RNAs in TCV- (left) and PLPV- (right) infected plants to illustrate the typical pattern of accumulation of genomic and sub-genomic RNAs in genera *Alphacarmovirus*, *Betacarmovirus*, and *Gammacarmovirus*, in the first case, and genus *Pelarspovirus*, in the second.

genes have identified the tombusvirids as a representative virus cluster for one of three RNA virus super-groups with relatedness to animal viruses of the family *Flaviviridae* and small RNA phages (*Leviviridae*).

Distribution, Host Range, Transmission, and Economic Significance

Carmo-like viruses are distributed worldwide and, with some exceptions, are reported to cause mild or asymptomatic infections in relatively restricted natural host ranges. Despite their usually moderate phenotypic effects, many of these viruses, although not all, accumulate to high concentrations in infected tissues.

Notwithstanding their narrow natural host ranges, carmo-like viruses have, in general, broad experimental host ranges that frequently include herbaceous plant species amenable to experimental manipulation. A number of carmo-like viruses have been identified in ornamental hosts. CarMV (genus *Alphacarmovirus*) is one of the most noteworthy, because its high incidence and wide geographical spread in cultivated carnations. PLPV (genus *Pelarspovirus*) and *Pelargonium flower break virus* (PFBV, genus *Alphacarmovirus*) are other examples of highly widespread viruses, in this latter case in *Pelargonium* spp., causing diseases either alone or in association with other viruses. Information on the prevalence of other carmo-like viruses affecting ornamentals, such as *Angelonia flower break virus* and *Calibrachoa mottle virus* (CMoV) (both in the genus *Alphacarmovirus*), HCRSV and *Japanese iris necrotic ring virus* (JINRV) (both in the genus *Betacarmovirus*), *Pelargonium chlorotic ring pattern virus*, *Pelargonium ringspot virus*, and *Rosa rugosa leaf distortion virus* (RrLDV) (the three of them in the genus *Pelarspovirus*), is more scarce. However, such prevalence is likely to be highly influenced by the distribution of the corresponding infected nursery stocks as most ornamental plants are vegetatively propagated. Illustrating the harmful effects that infection by these viruses may cause, the severe disease symptoms induced by HCRSV on ornamental hibiscus varieties has led to a massive removal of this type of plants from many recreational areas in Singapore. Interestingly, HCRSV also infects kenaf (*Hibiscus cannabinus* L.), an annual crop of major interest to the wood-pulp industry.

Legume species can also be naturally infected by several carmo-like viruses, such as *Nootka lupine vein clearing virus* (NLVCV, genus *Alphacarmovirus*), or *Cowpea mottle virus* (CPMoV), *Pea stem necrosis virus* (PSNV), and *Soybean yellow mottle mosaic virus* (SYMMV),

all three belonging to genus *Betacarmovirus*. The geographical distribution of each of these viruses does not seem very broad so far, with CPMoV being potentially the most important since it may seriously limit the cultivation of cowpeas that are important for food supply throughout Sub-Saharan Africa and particularly in Nigeria. On the opposite side, MNSV is considered to be an endemic virus in greenhouses and open-field systems for the production of cucurbits, significantly reducing yields and causing vast economical damage worldwide.

Two carmo-like viruses, TCV and *Cardamine chlorotic fleck virus* (CCFV) (genus *Betacarmovirus*), naturally infect *Brassicaceae* species. TCV is neither common, nor widespread in nature, whereas the known distribution of CCFV is limited to the Mount Kosiusko alpine region of Australia. Both are able to experimentally infect *Arabidopsis thaliana*, the most relevant model plant for basic plant research, in which they accumulate to extremely high concentrations, often approaching a level equivalent to 0.5% of the fresh weight of the plant tissue. *Honeysuckle ringspot virus* (HnRSV) and *Saguaro cactus virus* (SCV) (genus *Alphacarmovirus*), are presumably of little agricultural concern, and have been isolated from very particular hosts and areas, honeysuckle and San Luis Obispo (California) in the first case, and giant saguaro cactus from Sonoran Desert (Arizona), in the second. The infrequent isolation of these genetically similar viruses in remote locations around the world has prompted the speculation that ancestor carmo-like viruses may have been introduced into their natural hosts well before the last Ice Age and have since co-evolved in isolation in their diverse host plants.

Spread of carmo-like viruses may occur through infected soil, irrigation water, vegetative propagation, grafting and/or mechanical inoculation. In addition, transmission by biological vectors has been reported in some instances. Thus, TCV and CPMoV can be transmitted by beetles, PFBV by thrips and MNSV and PSNV by the root-inhabiting fungus *Olpidium bornovanus*. Seed transmission of carmo-like viruses is not well documented but it could also be an important factor for the distribution of, at least, MNSV and CPMoV.

Virion Structure and Assembly

The molecular structure of five carmo-like viruses (TCV, CarMV, CPMoV, HCRSV, and MNSV) has now been studied in detail, with TCV being the first studied by high-resolution X-ray crystallography. The detailed information about CP structure and inter-subunit interactions established that TCV and *Tomato bushy stunt virus* (TBSV, genus *Tombusvirus*) show remarkable structural conservation. In this regard, the common structural features shared by other members of the family *Tombusviridae* have been primarily deduced from alignment of the amino acid sequence of their CPs with those of TBSV and TCV. TCV consists of a $T=3$ icosahedral capsid of 180 subunits of the 38 kDa CP. The individual CP subunit folds into three distinct domains typical of CP subunit of tombusvirids. The relatively basic N-terminal R domain extends into the interior of the virus particle and presumably interacts with viral RNA. The R domain is connected by an arm to the S domain which constitutes the virion shell. The S domain is attached through a hinge to the P domain which projects outward from the virion surface. The resulting surface protrusions give the virions a bumpy appearance in electron micrographs.

TCV CP subunits are believed to form dimers in solution and during assembly. TCV is the only carmovirus for which detailed *in vitro* assembly studies have been performed. The virion has been shown to dissociate at elevated pH and ionic strength to produce a stable RNA–CP complex (rp-complex) and free CP subunits. Reassembly under physiological conditions in solution could be demonstrated using the isolated rp-complex and the soluble CP subunits. This rp-complex, consisting of six CP subunits tightly attached to viral RNA, could be generated *in vitro* and was shown to be important in selective assembly of TCV RNA. A model for assembly was proposed in which three sets of dimeric CP interact with a unique site on the viral RNA to form an initiation complex to which additional subunit dimers could rapidly bind. Preliminary characterization of the ‘origin of assembly’ for this virus identified two possible sites based on the identification of RNA fragments in the rp-complex protected from RNase digestion by CP. Further *in vivo* studies narrowed the assembly origin site to a bulged hairpin-loop of 28 nt within a 180 nt region at the 3′ end of the CP gene.

Genome Structure and Protein Functions

As mentioned above, complete nucleotide sequences of all virus species currently included in the genera *Alphacarmovirus* (7), *Betacarmovirus* (4), *Gammacarmovirus* (4), and *Pelarspovirus* (6) have been determined (Table 1). Comparative studies of the deduced ORFs revealed that all of these viruses encode a similar set of genes that are closely related and are present in the same gene order as illustrated in Fig. 2. Such set of genes is preceded by a 5′ non-coding region (NCR), whose length ranges between 5 nt (PLPV) to 134 nt (PSNV), and is followed by a 3′ NCR that varies from 224 nt (SCV) to 405 nt (NLVCV) in length. Distinct viral species do not share extensive sequence homology within these regions and none of them possesses neither a poly(A) tail nor a tRNA-like structure, in their 3′ end. In addition, the 5′ end of the genomes is not capped. The genome organization of the carmo-like viruses is quite compact and most of the identified ORFs are overlapping each other. As shown for one or more members of each genus, the product of the most 5′ proximal ORF (25–29 kDa) and its readthrough product (83–89 kDa, the RdRp) are essential for replication of the virus genome. In addition, all carmo-like viruses characteristically present two small ORFs in the middle of the genome that encode two proteins (6–13 kDa) involved in cell-to-cell movement (movement proteins or MPs). Both MPs have been proposed to function in a coordinate fashion, one recruiting the viral RNA and the other exploiting the plant

endomembrane system to promote intra- and inter-cellular movement of carmo-like viruses. The 3' proximal gene encodes the viral CP which varies from 37 to 42 kDa for the different viruses. Interestingly, as proven for several carmo-like viruses, including CarMV, MNSV, PFBV, PLPV, and TCV, this protein also acts as suppressor of RNA silencing, a potent antiviral mechanism in plants that is conserved in nearly all eukaryotic organisms. This function is performed by other viral products in other genera of the family *Tombusviridae*, underlining the uniqueness of the structural subunit of carmo-like viruses.

Although the genome organizations of all sequenced carmo-like viruses are very similar, those of pelarspoviruses are distinguished by some specific features such as the presence of a non-AUG start codon, instead of the canonical AUG, initiating the MP2 ORF and the lack of an AUG codon in any frame between the AUG initiation codon of MP1 and the CP ORFs. In addition, some individual carmo-like viruses display specific characteristics. For example, the two small central ORFs in MNSV (p7a and p7b) are connected by an in-frame amber codon that could result in the production of a 14 kDa fusion protein of the two ORFs by a readthrough mechanism. Similarly, a potential double readthrough could lead to translation of a C-terminal extended RdRp in the case of CarMV, HnRSV, PFBV, and JINRSV. On their side, genomes of CPMoV, HCRSV, SYMMV, and RrLDV contain a sixth ORF nested within the 3' proximal CP gene. Three-four additional small ORFs have also been predicted in RrLDV genome. Nevertheless, the biological functionality of most of these extra ORFs remains to be ascertained. Indeed, unequivocal proof of activity has only been provided for the novel ORFs that are nested within the RdRp and the CP gene, respectively, of HCRSV.

Replication and Gene Expression

Some carmo-like viruses, such as TCV, replicate to very high concentrations in protoplast infections, with the genomic (g) RNA accumulating to levels approaching that of the ribosomal RNAs. This facilitates identification and characterization of both *cis*-acting RNA elements and viral products involved in viral multiplication. For expression of genes located in internal and 3'-proximal positions of the gRNA, carmo-like viruses transcribe either one (genera *Alphacarmovirus*, *Betacarmovirus*, and *Gammacarmovirus*) or two (genus *Pelarspovirus*) 3'-coterminal sub-genomic RNAs (sgRNAs). In the first case, the larger sgRNA (~1.7 kb) functions as the messenger (m) RNA for the two MP genes utilizing a leaky-scanning mechanism whereas the smaller sgRNA (~1.5 kb) is the mRNA for the CP gene. When only one sgRNA (~1.7 kb) is produced, it serves as mRNA for translation of the two MP genes as well as the CP gene. Such translation is accomplished through leaky-scanning processes that are favored by the suboptimal translational context of the initiating AUG of the MP1 gene, the non-canonical start codon of MP2 gene (Fig. 2), and the lack of an AUG codon between the MP1 AUG and CP AUG. Both models for gene expression are supported by *in vitro* translation experiments performed with, at least, TCV, SCV, and PLPV. The number of sgRNAs (one or two) together with the monophyletic lineage of the encoded RdRps (Fig. 1) are the main criteria that define the distinct genera of carmo-like viruses.

As other viruses with RNA genome, carmo-like viruses are thought to replicate through a negative (–) strand intermediate because virus-specific double-stranded (ds) RNAs corresponding in size to the gRNA characteristically accumulate in infected plant tissue. As shown for TCV, the protein encoded by the 5' proximal ORF and its readthrough product are the only virus-encoded components of the polymerase complex. When expressed from two separate mRNAs, both viral products complemented in *trans* to enable the genome replication. Besides interactions between viral products, the assembly of viral replicase complexes (VRCs) involves intricate interactions between viral and host factors, including cellular membranes that serve as platforms for the formation of VRCs. Associations of the VCRs of PFBV and MNSV with mitochondrial membranes have been described. The VRCs also catalyze synthesis of sgRNAs most likely through a premature termination mechanism, as suggested from results with TCV and PLPV. This mechanism involves generation of a sg (–) strand on a genomic (+) template because of the presence of a structural motif in the latter that causes the RdRp to pause before it reaches the template 5' end. The sg (–) molecules serve as templates for generation of sg (+) RNAs. A membrane-containing extract prepared from evacuated protoplasts of uninfected *Arabidopsis* plants has been shown to faithfully produce both genomic and sub-genomic RNAs from a full-length TCV RNA template. Such an extract may be useful for future characterization of viral as well as host elements required for virus replication and transcription.

Numerous studies have demonstrated that, besides the virus-encoded proteins, a plethora of structural elements in the viral RNA play critical roles in the genome replication of carmo-like viruses. These elements are located throughout the entire viral genome and occur in both the (+) and (–) strands. Their roles range from promoters, enhancers or repressors for RNA replication and transcription, enhancers for translation, signals for readthrough translation and specificity determinants for virus assembly. The current knowledge of these RNA structures suggests that different secondary, or even tertiary, structural motifs, some of them mutually exclusive, are formed at the different stages of virus multiplication, and the highly coordinated nature of their formation ensures optimal utilization of the compact viral genome.

Satellites, Defective-Interfering RNAs

TCV is the only carmo-like virus in which replication of associated small subviral RNAs in infected plants has been characterized, and the situation for this virus is curiously complex. TCV infections are associated with defective interfering (DI) RNAs derived totally from the parent genome (e.g., RNA G of 342–346 nt), satellite (sat) RNAs of non-viral origin (e.g., RNAs D, 194 nt and F, 230 nt), and chimeric RNAs (e.g., RNA C of 356 nt) with a 5' region derived from sat RNA D and a 3' region derived from the 3' end of the TCV genome. All three types of small RNAs depend on the helper virus for their replication and encapsidation within

the infected plant. The different satellites and DI RNAs have been shown to affect viral infections in different ways. Both RNAs C and G intensify viral symptoms while interfering with the replication of the helper virus, while RNAs D and F seem to produce no detectable effects on either expression of symptoms or helper virus replication.

Virus–Host Interaction

Considerable progress has been made in the last two decades in our understanding of the molecular mechanisms of virus–plant interactions with significant contributions coming from studies utilizing TCV and its host plant *Arabidopsis*. Most notably, one ecotype of *Arabidopsis thaliana* has been determined to be resistant to TCV infection and the resistance gene (HRT) and its encoded protein have been characterized. Additional host factors that contribute to the resistance response have also been elucidated including the identification of a novel transcription factor (TIP) whose interaction with TCV CP is critical to prevent basal resistance. The determination that TCV CP is targeted by HRT resistance protein suggests that TCV CP plays a key role in combating antiviral defense mechanisms of the plant host, in addition to being required for virus assembly. Indeed, as mentioned above, distinct studies have established that TCV CP is a strong suppressor of RNA silencing, a host defense mechanism that targets invading RNA. TCV CP seems to develop this suppressor function through different mechanisms, one of which consists in interacting with Argonaute (AGO) proteins, the key effectors of RNA silencing. In addition, it has been reported that TCV CP requires RAV2, an ethylene inducible factor, for suppression of RNA silencing. The role of RNA silencing in the fight against TCV has been also evidenced by the high accumulation of suppressor-deficient TCV mutants in *A. thaliana* plants lacking either AGO1 or one or more of the four Dicer-like enzymes (dsRNA-specific endoribonucleases that play an essential role in triggering RNA silencing).

Besides host factors involved in the resistance response against TCV, a host factor that most likely assists the virus during its life cycle has been identified. This factor corresponds to eukaryotic translation initiation factor (eIF) 4G of *Arabidopsis* that has been found to augment TCV accumulation, presumably by promoting more efficient translation of viral genes. In case of MNSV, genetic and biochemical evidence showing that translation is eIF4E-dependent in melon has been obtained.

Similarly to that found for the CP of TCV, the CP of PLPV, which also acts as RNA silencing suppressor, interacts with AGO proteins. Interestingly, this PLPV viral product has been reported to interact as well with distinct importins alpha that are crucial nuclear-transport receptors. Such interaction seems to favor the accumulation of PLPV although the precise underlying molecular mechanism remains to be known.

Other relevant aspect of virus-host interactions refers to symptom elicitation. This question has been particularly tackled with TCV and its satellite RNA C. It has been shown that TCV CP is important in satellite RNA C interactions in the host plant. Normally, the presence of RNA C results in symptom intensification in TCV infections. However, when the TCV CP ORF is either deleted or replaced by the CCFV CP ORF, RNA C attenuates symptoms caused by the helper virus suggesting that CP either downregulates the replication of RNA C or enhances its own competitiveness.

Finally, the replicase gene of TCV has also been implicated in the symptom modification by satellite RNA C by two independent groups. The 3′ end of the TCV genome, a sequence common in TCV RNA, RNA C, and DI RNA G, was also suggested to be a symptom determinant.

Recent results also suggest that viral pathogenesis could be related with virus-induced alterations in the levels of long non-coding RNAs, which are involved in diverse and substantial biological processes, and/or of microRNAs, small RNAs that act as developmental regulators. In this context, floral structure disorders typically observed in TCV-infected *A. thaliana* plants have been correlated with upregulation of a long noncoding RNAs which, in turn, seems to lead to downregulation of a floral structure-related APETALA2 gene. However, changes in levels of regulatory RNAs induced by viral infections do not always correlate with phenotypic effects as shown with PLPV-infected *Nicotiana benthamiana* plants which, despite being asymptomatic, exhibited modifications in microRNA contents. These observations underline the complexity and the multiplicity of factors that may be involved in viral pathogenesis.

Cassava Brown Streak Viruses (*Potyviridae*)

Basavaprabhu L Patil, ICAR–Indian Institute of Horticultural Research, Bengaluru, India

© 2021 Elsevier Ltd. All rights reserved.

Nomenclature

aa Amino acid(s)
amiRNAs Artificial microRNAs
Cas9 CRISPR-associated nuclease 9
CBSD Cassava brown streak disease
CMGs Cassava mosaic geminiviruses
CRISPR Clustered regularly interspaced short palindromic repeats
eIF4E Eukaryotic translation initiation factor 4E
HAM1h Homologue of HAM1

HCPPro Helper component proteinase
kDa Kilo dalton
NGS Next generation sequencing
Nia Nuclear inclusion protein a
Nib Nuclear inclusion protein b
nt Nucleotide(s)
NTP Nucleoside triphosphate
RNAi RNA-interference
siRNAs Small interfering RNAs
VPg Viral protein-genome linked

Glossary

Artificial microRNAs They are similar to micro RNAs, that are single-stranded, ± 21 nt long, and designed by replacing the mature miRNA sequences of duplex within precursor-miRNAs.
CRISPR-associated nuclease 9 A genome editing technology.
Eukaryotic translation initiation factor 4E An eukaryotic translation initiation factor involved in directing ribosomes to the cap structure of mRNAs.
Gene silencing A method to regulate gene expression to prevent the expression of a targeted gene.
Genome editing A method to edit the gene employing different editing technologies.
HAM1-like sequence A gene that protects against the mutagenic effects through detoxification of abnormal pyrimidine as well as purine nucleotides.
Helper component proteinase A multifunctional protein encoded by viruses of the genus *Potyvirus* and other viruses of the family *Potyviridae*, involved in aphid transmission, polyprotein processing, and suppression of host antiviral RNA silencing.
microRNA A type of small non-coding RNA of ± 21 nt in size involved in gene regulation and gene silencing.
Next generation sequencing A ultra-high throughput massively parallel sequencing technology.

Nuclear inclusion protein a It is one of the proteases encoded by potyviruses.
Nuclear inclusion protein b It is a RNA-dependent RNA polymerase encoded by potyviruses.
Phytosanitation It is one of the plant disease management strategy that involves removal and destruction of diseased plant parts to prevent further spread of the pathogen.
RNA silencing Sequence-specific regulation of gene expression triggered by double-stranded RNA, also termed RNA-interference (RNAi).
Silencing suppression Gene silencing suppression mechanism by certain specialized proteins encoded by plant viruses.
Small interfering RNAs A class of double-stranded non-coding RNA molecules, 20–25 base pairs in length, operating within the RNA interference pathway.
Transgenic plants Transgenic or genetically modified plants have genes that are derived from another species inserted into their genome through recombinant DNA technology.
Viral protein-genome linked A potyviral multifunction protein covalently linked to 5' end of viral RNA, which interacts with the eukaryotic translation initiation factor eIF4E, a cap-binding protein, which is imminent for virus infection.

Introduction

There are at least 20 different viruses that infect the tropical plant cassava (*Manihot esculenta* Crantz), of which the cassava infecting begomoviruses and the brown streak associated ipomoviruses are the economically most important viruses resulting in monetary loss exceeding US\$ 1 billion per year. Here in this article we intend to describe and discuss about the ipomoviruses associated with the cassava brown streak disease (CBSB) in Africa. Although the first report of CBSB was in 1930s from the coastal region of Tanzania, it did not receive much attention since it was restricted to the coastal lowlands of east Africa and appeared sporadically. However, post 2004, CBSB has been spreading to several parts of Africa putting the food security of millions of Africans at stake.

Aetiology, Host Range and Transmission

CBSB is known to affect cassava alone, while it has also shown its presence in the wild relative of cassava *Manihot glaziovii*. CBSB does not have any known alternate hosts and it is not known to infect weed species. However, under artificial inoculation

Fig. 1 Symptoms of CBSD on Root and Leaves of cassava. (a). Brown streaks on the young stem, (b) Different types of feathery chlorosis on leaves, (c) Constrictions on the root surface, (d) Necrosis in the roots. Adapted with minor modification from Patil, B.L., Legg, J.P., Kanju, E., Fauquet, C.M., 2015. Cassava brown streak disease: A threat to food security in Africa. *Journal of General Virology* 96, 956–968.

conditions, it can infect some of the herbaceous hosts and the model host *Nicotiana benthamiana*, widely used in virology studies. Two diverse and distinct ipomovirus species *Ugandan cassava brown streak virus* (UCBSV) and *Cassava brown streak virus* (CBSV) are known to cause CBSD, either as independent infection or sometimes as mixed infections. In this article both UCBSV and CBSV isolates are sometimes collectively referred as CBSVs. The most common symptoms on the foliage is feathery chlorosis along the veins of the oldest leaves, occasionally with circular patches of chlorosis in between the primary veins (Fig. 1(b)), while the stem shows characteristic brown necrotic streaks and stem die-back in severe cases (Fig. 1(a)). Young leaves do not show symptoms. However, CBSVs cause major damage in the tuberous roots, the edible part of cassava. CBSD affected tuberous roots show brown corky necrosis in the starchy tissue, resulting in reduction of starch and cyanide content, occasionally the tuberous roots develop radial constrictions (Fig. 1(c)). However, the symptoms can vary depending on the virus isolate involved, cassava genotype and its age, and the prevailing environmental conditions. In one of the studies involving mechanical inoculation of diverse CBSV/UCBSV isolates showed production of variable symptoms in both the natural host cassava and the model host *N. benthamiana*.

Comparison of symptom severity of CBSV and UCBSV indicated CBSV to be more virulent, causing necrosis in *N. benthamiana*, while sap inoculation of UCBSV induced mosaics and rugosity. Similar comparative studies in cassava by grafting of infected

scions showed CBSV to be more virulent than UCBSV, and the CBSV infected stem cuttings significantly reduced the cassava sprouting, as a result of higher virus accumulation in case of CBSV infection compared to infection by UCBSV. Agro-infiltration of infectious clones of cassava mosaic geminiviruses (CMGs) followed by sap inoculation of UCBSV indicated a synergistic interaction between the geminivirus and ipomoviruses in the case of *N. benthamiana*, however there are no reports of synergism in field situation.

Initially, *Bemisia afer* (Priesner-Hosny) was presumed to be the vector for CBSD transmission, since they were predominantly present on lower leaves of cassava, where the CBSD symptoms are prominent. Later, experiments showed that the whitefly (*Bemisia tabaci* (Gennadius)) was the vector transmitting CBSVs. It was capable of transmitting this ipomovirus in a semi-persistent manner unlike persistent transmission of the geminiviruses. The transmission studies done in the lab conditions showed that the CBSVs were acquired in 5–10 min and retained by the whiteflies for less than 48 h. A maximum transmission of 60% could be achieved by using 20–25 viruliferous whiteflies per plant and the virus spread in the field was maximum up to a distance of 17 meters per cropping season. This study clearly indicates that the whitefly vectors could transmit CBSVs semi-persistently and only for a short distance, while the long-distance transmission of CBSD was mostly through transportation and use of infected planting material.

Effective virus diagnostics is of utmost importance for accurate disease forecasting and management of any disease outbreaks. Early and accurate detection of CBSVs in infected cassava is a great challenge. There are several molecular methods for diagnostics of CBSD, of which ELISA and its modified versions are common. Using ELISA based techniques it is difficult to differentiate between CBSV and UCBSV. However, PCR based techniques such as RT-PCR, multiplex RT-PCR, Real Time PCR and loop-mediated isothermal amplification are developed to detect and differentiate CBSVs and UCBSVs. Sequences of several unknown viruses including CBSVs have been unraveled by next generation sequencing (NGS) strategies.

Current Status of CBSD in Africa

The first report of CBSD was from cassava cultivated in the Usambara mountains of Tanzania. Subsequent surveys showed that CBSD was prevalent in almost the entire coastal lowlands of East Africa, stretching from north-eastern border of Kenya, to the Tanzanian border with Mozambique, and lower altitudes of Malawi. CBSD incidence was not recorded in inlands above an altitude of 1000 m above sea level (a.s.l) and hence for a long time CBSD was considered as a low altitude disease. However, subsequent studies in 2004 have shown that CBSD was more widespread and also present at altitudes beyond 1000 m a.s.l., such as Uganda, western Kenya, north-western Tanzania, Burundi and the Democratic Republic of Congo.

A countrywide systematic survey for incidence of CBSD in Tanzania was done in 1994 and the maximum incidence was recorded from southern lowland coastal districts of Mtwara (36%) and Masasi (25%), while CBSD was completely absent in higher altitudes of north-western Tanzania. Contrastingly, at the same time CBSD symptoms were reported in cassava cultivated at altitudes 1200 m above sea level, in a location near Entebbe in central/southern Uganda and also from Tabora in north-western Tanzania. Except for these reports of occurrence of CBSD at higher altitudes the notion that CBSD is a low altitude disease remained unchanged until the time a major report on occurrence of CBSD was made from central/southern Uganda in 2004.

An unpublished estimate by NARO (Uganda) put the overall incidence of CBSD at 16% in 2008 and 29% in 2009, clearly depicting significant spread of CBSD in East Africa. Similar such reports on spread of CBSD were made in western Kenya and Lake Victoria zone of Tanzania. Surveys for CBSD were done in 19 districts of Tanzania and revealed a drastic increase in CBSD incidence in north-western regions of Tanzania.

In recent years, additional reports have been made from Rwanda, Burundi and the eastern Democratic Republic of Congo (DRC). In early 2000, symptoms similar to CBSD have also been reported from cassava cultivated in Bas Congo Province in western DRC, Mulanje Province in central Angola and parts of Madagascar. However, none of these reports has been confirmed for the presence of CBSV by using appropriate diagnostic tools. All of these surveys were primarily based on visual assessments of leaf symptoms, and they may be underestimates of the true level of CBSV infection, since under the unfavourable weather conditions the CBSD leaf symptoms may not be expressed.

Genome Organization and Gene Functions

The viruses involved in CBSD belong to the family *Potyviridae* and the genus *Ipomovirus*. The family *Potyviridae* is one of the largest families of plant viruses, consisting of six genera, classified based on their genome organization, sequence similarity and insect vectors involved in their transmission. Infected tissues with ipomoviruses show characteristic pinwheel-like structures or cylindrical inclusions within the phloem tissue, typical of potyviruses. Similar to other viruses of *Potyviridae* family, both the ipomoviruses CBSV and UCBSV have a positive-sense single stranded RNA genome with an average length of 9 Kb. All the viruses of the *Potyviridae* family except for the members of the genus *Bymovirus* have monopartite genome, which is translated into a single polyprotein which is later proteolytically autocleaved into ~10 mature proteins by three distinct proteases expressed by the virus itself.

Since the first report of CBSD in 1935, the first complete genome sequence of an ipomovirus involved in CBSD was published in 2009. This isolate from Tanzania sampled in 2007 was an Ugandan cassava brown streak virus isolate abbreviated as UCBSV-[TZ:MLB3:07] with a sequence length of 9069 nt, which was shorter than other ipomoviruses. This UCBSV genome has 134 nt and 226 nt untranslated regions (UTRs) on both of its ends referred as 5'UTR and 3'UTR respectively (Fig. 2(b)). These UTRs

Fig. 2 (a) Depiction of endemic (red-striped) and epidemic zones (blue-striped) of CBSV and UCBSV in East Africa, (b) A representative picture showing the genome organization of CBSV/UCBSV encoding for 10 proteins (P1, first serine proteinase; P3, third protein; 6K1 and 6K2, two 6 kDa proteins; CI, cylindrical inclusion protein; VPg, viral protein genome-linked; NIa-Pro, main viral proteinase; NIb, replicase; HAM1, Maf/HAM1 pyrophosphatase homologue; CP, coat protein) and 3' and 5'UTRs, the poly(A) tail and PIPO translated by +2 frame shift within the P3. Two amino acids at the proteolytic cleavage sites of the polyprotein are shown below the polyprotein, and the estimated molecular mass (in kDa) for each protein is given in the box, (c, d) Phylogenetic analysis of selected CP sequences and the complete genome sequences of CBSV/UCBSV isolates. GenBank accession numbers are indicated and the scale bar represents the pairwise distance expressed as percentage dissimilarity. Adapted from Patil, B.L., Legg, J.P., Kanju, E., Fauquet, C.M., 2015. Cassava brown streak disease: A threat to food security in Africa. *Journal of General Virology* 96, 956–968.

encompass the regulatory sequences involved in viral gene/protein expression. Later a second distinct ipomovirus species named as Cassava brown streak virus (CBSV), with a sequence length of ~9008 nt, with similar genome organization as UCBSV, was also found to be involved in CBSV.

Unlike other members of the *Potyviridae* family, both the above ipomoviruses infecting cassava encode for a single P1 serine proteinase and are devoid of helper component cysteine proteinase (HCPro) (Fig. 2(b)). Such a high level of diversity in the P1 gene is characteristic of viruses of the *Potyviridae* family. The P1 of CBSVs are most similar those of another ipomovirus species called *Sweet potato mild mottle virus* (SPMMV). However, in contrast to CBSVs, the SPMMVs possess the HCPro, indicating it to be an evolutionary link between ipomoviruses and potyviruses. In contrast to both CBSVs and SPMMVs, another two ipomovirus species, namely *Cucumber vein yellowing virus* (CVYV) and *Squash vein yellowing virus* (SqVYV) possess two P1 serine proteinases (P1a and P1b). Silencing suppression studies done by individually expressing the CBSV genes has demonstrated P1 to be a silencing suppressor for CBSVs. The P1 of CBSVs encompass the basic LxKA and Zn-finger motifs, and the LxKA motif of P1 is diverse within different ipomoviruses, with exchanges of lysine (K) and arginine (R) at positions 2 and 3, and in the case of CBSVs, the P1 protein contains LRRs. Whereas in case of SPMMV although the P1 protein has the silencing suppression activity, the

HCPPro is also known to extend the durability of the silencing suppression. Whereas in the case of ipomoviruses lacking HCPPro, the P1b protein complements for the silencing suppression activity.

The other eight ORFs namely, P3 (the third protein), 6K1 and 6K2 which code for the two 6 kDa proteins, the cylindrical inclusion protein (CI), viral protein genome-linked (VPg), the main viral proteinase (NIa-Pro), the replicase (NIb) and the coat protein (CP) of CBSVs are more similar to the other ipomovirus sequences such as CVYV (*Cucumber vein yellowing virus*), SqVYV (*Squash vein yellowing virus*) and SPMMV. A recently reported potyviral protein P3N-PIPO expressing by 2 nucleotide frameshift within the P3 ORF is also found in CBSVs. Both CI and P3N-PIPO complex coordinate the intercellular movement of potyviruses by formation of plasmodesmata-associated structures.

In addition to the above described proteins, there are nine ORFs in CBSVs which are characteristic of the *Potyviridae* family. In addition, they contain an unusual ORF called as HAM1, encoding a polypeptide of 226 aa, flanked by proteolytic cleavage sites, and it is placed in between the replicase (NIb) and the CP. This additional ORF had homology with the Maf/HAM1 superfamily of proteins reported in several prokaryotes and eukaryotes, which are nucleoside triphosphate (NTP) pyrophosphatases. These proteins are known to reduce mutations by intercepting non-canonical forms of NTPs and thus prevent their incorporation into nucleic acids, which otherwise may result in unfavourable mutations. *Euphorbia ringspot virus* belonging to the *Potyvirus* genus is the only other viral species reported to contain an HAM1-like sequence. The presence of such an anti-mutator gene may have a beneficial role under oxidative stress conditions, during which mutations occur rampantly. Such a scenario may exist in the plants belonging to the Euphorbiaceae family, particularly the older leaves with higher levels of senescence where CBSVs are shown to accumulate. *Blackberry virus Y*, another species of the *Potyviridae* family is also known to contain such unusual heterologous sequences encompassing the AlkB domains within their P1 proteinase, which may also counter the occurrence of deleterious mutation. The presence of such AlkB domains are also known to be present in some of the viruses of the families *Flexiviridae* and *Closteroviridae*.

However, a more recent investigation about the properties of Ham1 protein of CBSVs by *in vitro* and *in vivo* overexpression has indicated Ham1 to be a necrosis determinant. *In vitro* enzyme assays showed that the Ham1 proteins of both CBSV and UCBSV had ITPase activities. However, deep sequencing experiments did not show any evidence of Ham1 mutagenic protection during infection in *N. benthamiana*. Deletion and mutation studies with an infectious clone for an isolate of CBSV from Tanzania showed that knock out of Ham1 in CBSV failed to produce necrotic symptoms in the model host *N. benthamiana*. Thus it was proposed that the Ham1 of CBSVs with highly conserved ITPase motifs may have a highly selectable function during infections in cassava and may represent a euphorbia host adaptation that could be targeted in antiviral strategies.

Evolution, Diversity and Distribution of Viruses Involved in CBSD

Phylogenetic analysis of the CBSV/UCBSV CP sequences from East Africa resulted in the formation of two distinct clusters, with all the CBSV CP sequences clustering together and the UCBSV CP sequences forming another distinct cluster (Fig. 2(c)). To date, 27 complete genome sequences of CBSVs are available in the NCBI database, and of these sequences, 11 are UCBSV isolates and 16 are isolates of CBSV. These sequences are isolated from 6 East African countries, 5 from Uganda, 14 from Tanzania, 3 from Mozambique, 3 from Comoros Islands, and one each from Kenya and Malawi (Fig. 2(a)). All the sequences are mostly of 9 Kb length, with minor variation in their sizes, the smallest one reported is 8748 nt long and the longest one is 9097 nt. Phylogenetic analysis of the full length sequences of CBSV/UCBSV also result in the formation of two main clusters corresponding to CBSV and UCBSV isolates and these major clades are further subdivided into minor clades. The cluster with UCBSV isolates has more sub-clusters than the CBSV species, though the genomes of CBSV isolates are genetically more diverse than those of UCBSV and the evolutionary rate of CBSV is considered to be much higher than UCBSV. Recent studies indicate that the accelerated rate of evolution is mainly contributed by *NIa*, *6K2*, *NIb* and *P1* sequences. *P1* was the highest contributor to diversity of CBSVs and phylogenetic analysis of N-terminal sequences of *P1* gene alone with advanced bioinformatics tools revealed the presence of a third distinct clade tentatively called as CBSV-Tanzania (CBSV-TZ).

Sequence comparison of the complete genomes of CBSV and UCBSV isolates revealed an identity range of 69.0%–70.3% at the nucleotide level and 73.6%–74.4% at the polyprotein amino acid sequence levels. Thus, in view of the sequence divergence between these two groups, two distinct virus species are recognized, CBSV and UCBSV (Fig. 2(d)). While the nucleotide sequence identities among the UCBSV isolates ranged from 87% to 99% and among the CBSV isolates it was 79%–95%. Recombination analysis using RDP4 for all the CBSV and UCBSV sequences indicated 11 recombination events within CBSV isolates and 3 in UCBSV. There was at least one recombination in each of the ten genes, with maximum recombinations (5) detected in CP followed by CI. However, till date no recombinations have been detected between the CBSV and UCBSV isolates, which is consistent with the previous reports on absence of recombination between diverse genomes of RNA viruses due to reduced fitness in the recombinants. The size of the gene sequences that encoded for CI, VPg and CP proteins was variable among isolates of CBSV and UCBSV.

The amino acid sequence identity for HAM1 sequences between CBSV and UCBSV was 55%, which was lowest among all gene sequences of the viruses. Such a low identity may indicate that both the Ham1 sequences may have been acquired from two different hosts at two different time points or they may have evolved rapidly than the other genes as evidenced by adaptive selection pressure on HAM1 of both CBSV and UCBSV. Sequence analysis revealed that there are 33 highly conserved amino acid

residues across HAM1 homologues from different organisms, indicating a strong negative selection on HAM1 and CP genes. The CP of CBSV was 9 aa longer than the CP of UCBSV and the size of P1 protein was also highly variable, with only ~60% aa identity between isolates of the two species. These size differences in the CP sequences may have an implication on their differential transmission by the whitefly vector. Although the transmission of CBSVs by whiteflies is well established under experimental conditions the differential transmission efficiency by whiteflies between the two viruses has not been significant. A recent report on detailed sequence analysis for several CBSV isolates revealed the presence of the DAG motif in their CP genes, however such a motif was not recorded in the UCBSV CP sequences. DAG sequences are present in the HCPro encoded by all the potyviruses which is an important determinant for aphid transmission. Hence it needs to be experimentally verified if aphids are capable of transmitting the CBSVs or if it is most probably an evolutionary mark in the CP of the ipomoviruses. The diversity in the P1 sequences may result in variation in their ability to suppress RNA silencing and which may have a correlation with the virulence of CBSV and UCBSV isolates.

Although in the fields there are no apparent symptom differences among the isolates of CBSV and UCBSV, under controlled conditions distinct phenotypes are produced by CBSV and UCBSV isolates. Mixed infections are found in regions where both CBSV and UCBSV are found. However, there is no evidence of synergistic interaction between the isolates of CBSV and UCBSV, unlike the interaction between different species of cassava infecting geminiviruses.

A RT-PCR based study in 2014, in eight major districts of Rwanda on distribution of CBSVs revealed that single infections of cassava by UCBSV were most common (74.2%) and were associated with wide range of symptom phenotypes. However, single infections by CBSV were predominant (15.3%) in plants showing CBSD symptoms on stem alone, while mixed infections of CBSV and UCBSV were in 10.5% of the total number of plants infected and were predominantly present in combinations of leaf + stem + root phenotypes. Further, phylogenetic analysis of a partial sequence of CP of all the isolates in this study indicated that in Rwanda there is only one type of CBSV while diverse types of UCBSVs are involved in CBSD.

Management and Control of CBSD

Phytosanitary practices are most important for virus free cultivation of cassava, because of its high vulnerability to virus transmission. In this regard the group led by Dr. James Legg based in the CGIAR institute IITA (Tanzania) is playing a major role in containing CBSD spread. CBSD is transmitted by the whitefly vectors for a shorter distance since the mode of transmission of these ipomoviruses is semi-persistent in nature. While long distance transmission of CBSD can only happen through long distance movement of vegetative propagules. Some of the important steps for control of CBSD are production of clean or disease free planting material, virus indexing of parent material and the pre-basic germplasm propagation, and regular roguing of diseased plants. Further, cooperation among group of farmers at a community level is important for a collective action and implementation of phytosanitary measures. Currently, such large scale initiatives are being implemented in Eastern and Southern Africa, and efforts are made to contain the regional spread of CBSD. Further, national and regional quarantine measures are enforced to prevent spread of CBSD during exchange of cassava germplasm.

Sources of CBSD Resistance and Their Introgression

Crop improvement through resistance breeding has been the most successful approach for control of crop diseases. Although, breeding for virus resistance in cassava was initiated in 1935 at Amani, Tanzania; it has been a major challenge since cassava is cross pollinated, with high level of heterozygosity. In this breeding programme, 46106/27 was the most CBSD resistant cassava variety developed by backcrossing *M. glaziovii* with *M. esculenta*. This is one of the most successful products of the research programme at Amani, presently cultivated by the farmers and this CBSD resistance still persists in the farmers' fields in Kenya, which locally is called as Kaleso.

Hundreds of SNP markers have been developed for CBSD tolerance and a linkage map has also been developed which is used for detection of CBSD tolerant quantitative trait loci (QTLs). Mapping populations developed by crossing CBSD-tolerant cultivar, Namikonga and a susceptible cultivar, Albert are being used for identification of QTLs associated with CBSD resistance. Now that cassava genome sequence is published, it could be used for identifying genes that control CBSD resistance and for development of new markers associated with CBSD resistance. Next generation sequencing technologies are also being employed for identification of genes associated with CBSD tolerance or the genes that respond to CBSD infection. Gene expression studies, using cassava varieties with differential resistance to CBSD revealed that at least 700 genes were overexpressing in the CBSD resistant variety Kaleso when compared to the susceptible variety Albert. Although none of these differentially expressed genes resembled a known disease resistance gene, many of them encoded enzymes or factors involved in hormone signalling or secondary metabolites pathways, that may be associated with disease resistance. However, none of the cassava genotypes/hybrids identified are immune to CBSD, but majority of them are tolerant since they show clear foliar symptoms, but necrosis in the roots is absent or delayed.

In one of the recent studies, 238 cassava germplasm accessions from South America were screened for CBSD resistance. There were 7 South American accessions that were completely free of CBSD symptoms and were negative for RT-PCR detection. The breeding lines DSC167 and DSC188 showed broad spectrum resistance to diverse isolates of CBSVs. This clearly reflects that

Fig. 3 (a) Screening of RNAi-based transgenic *N. benthamiana* for resistance against CBSVs (b) Confined field trials for RNAi-based transgenic cassava lines in Uganda, (c, d) Brown necrotic lesions seen on the stems of CBSV-infected control cassava plants, compared with non-infected transgenic cassava, (e, f) Cross section of cassava roots showing CBD symptom distribution in non-transgenic vs transgenic cassava plants, (g) accumulation of small interfering (si)-RNA in transgenic cassava as revealed by Northern hybridization technique. Adapted from Patil, B.L., Legg, J.P., Kanju, E., Fauquet, C.M., 2015. Cassava brown streak disease: A threat to food security in Africa. *Journal of General Virology* 96, 956–968.

the germplasm collections are potential reservoirs of several disease resistance genes and their conservation is critically important for resistance breeding programmes.

A project led by the International Institute of Tropical Agriculture (IITA) aims to ensure that the farmers in Africa have access to diverse disease-free improved cassava varieties with resistance to both CBD and CMD, and with consumer preferred traits. Studies have revealed that both additive and non-additive genetic effects are required for expression of CBD resistance trait, and of several crosses studied, the cassava variety Kaleso (Namikonga) had the best general combining ability for CBD resistance.

Engineering CBD Resistance

Although there are sources of resistance against CBD, it could be impossible to introgress CBD resistance while retaining the original agronomic/quality traits of cassava. Furthermore, the resistance reported against CBD is more of tolerance to virus infection, rather than immunity against the CBSVs. Hence, genetic engineering is an important option for controlling plant viruses and CBSVs in particular. There are several strategies used for control of viruses that infect plants, which will not be elaborated here, since it is an extensively reviewed topic. The first successful control of CBSV was demonstrated using RNA-interference (RNAi) strategy (Fig. 3), result confirmed later by other groups.

Similarly, CBD resistance has been accomplished by over-expression of artificial micro RNAs that targeted the CBSVs, however this work was restricted to the model host *N. benthamiana*. An interaction between the viral genome-linked protein (VPg) and host eukaryotic translation initiation factor 4E (eIF4E) isoforms is pre-requisite for a potyvirus to establish infection in a host cell.

Recently, the CRISPR/Cas9-mediated genome editing was employed to alter the sequence of cassava eukaryotic translation initiation factor 4E (eIF4E) isoforms, namely ncbp-1 and ncbp-2. When the ncbp-1/ncbp-2 cassava mutants were challenged with CBSV, there was a delay in symptom development, as well as reduced severity and incidence of storage root necrosis, which corresponded with reduced virus titer in storage roots. However, despite all these very positive results showing the possible control of CBSV through biotechnology, none of the putative commercial products have been distributed to farmers so far, due to the lack of a biotechnology official framework in East African countries to permit its use in safe conditions.

Ren Replication enhancer protein

siRNA Small interfering RNA

ssDNA Single-stranded deoxyribonucleic acid

TrAP Transcriptional activator protein

Glossary

Nonanucleotide A codon containing nine nucleotides.

Pandemic An outbreak of a disease over several countries or a large part of the world.

Pseudo-recombinant A viral infection involving complementary genome components from different virus species.

Taxonomy

Cassava mosaic viruses belong to the genus *Begomovirus* in the family *Geminiviridae* which comprises viruses with single-stranded circular DNA genomes that are transmitted by *Bemisia tabaci* (Gennadius) whiteflies. The cassava-infecting begomoviruses have two DNA components (DNA-A and DNA-B) of which the DNA-A genome sequences are used for taxonomic assignment of virus species. The species demarcation threshold is at 91% sequence identity, thus virus genomes having less than 91% of nucleotides on DNA-A that are identical to those of their closest neighbor are assigned to a unique species. Eleven cassava mosaic geminiviruses (CMGs) are currently recognized as distinct virus species by the ICTV (See Relevant Websites Section). These are: *African cassava mosaic virus* (ACMV), *East African cassava mosaic virus* (EACMV), *South African cassava mosaic virus* (SACMV), *Indian cassava mosaic virus* (ICMV), *Sri Lankan cassava mosaic virus* (SLCMV), *East African cassava mosaic Malawi virus* (EACMMV), *East African cassava mosaic Cameroon virus* (EACMCV), *East African cassava mosaic Zanzibar virus* (EACMZV), *East African cassava mosaic Kenya virus* (EACMKV), *Cassava mosaic Madagascar virus* (CMMGV), and *African cassava mosaic Burkina Faso virus* (ACMBFV) (**Table 1**; **Fig. 1**). Several of these originated from recombination events that generated genomic diversities beyond species boundaries. The names given reflect the relatedness to their putative parental virus.

Intraspecific Diversity

New, recombinant cassava viruses described provide evidence for on-going diversification of CMG genomes. Interspecific recombination of DNA-A and DNA-B genome components of cassava viruses also include sequences from other begomoviruses. For example, genome portions of the monopartite Tomato leaf curl virus are present in ACMBFV. Similarly, the genome components of CMMGV include, besides elements from other CMGs, sequences from non-related monopartite begomoviruses infecting tomato in the Indian Ocean islands. Additionally, there is ample evidence for molecular diversity of CMG genomes from complete DNA-A and DNA-B genome sequences of virus isolates available in GenBank. Nevertheless, in spite of contrasting molecular characteristics, there is little evidence for unique biological features of each of the virus species in terms of their symptom phenotypes, natural host range, transmission parameters or the association of particular virus isolates with *B. tabaci* species that would provide additional information for the discrimination of virus strains or the identification of a particular virus species. The 11 acknowledged CMG species and the numerous isolates that are present in Africa and Asia are merely characterized by distinctive sequences of their DNA-A genome components.

Fig. 1 Estimated phylogeny of DNA-A genome sequences of cassava mosaic geminivirus species within the genus *Begomovirus*, family *Geminiviridae*. The evolutionary history was inferred using the Maximum Likelihood method with the percentage of trees in which the associated taxa clustered together shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. The evolutionary analyses were conducted in MEGA X.

History

Cassava (*Manihot esculenta* Crantz) is a root crop that is grown widely throughout the tropics, primarily for its value as a starchy staple food. From its origins in Latin America, cultivated cassava was introduced to Africa in the sixteenth century, and subsequently spread through much of Africa south of the Sahara. The first cultivation of cassava in Asia occurred in south India in the

19th century, before it spread more widely throughout South-East Asia and eventually as far as Southern China. Although initially used as a food crop, most cassava in Asia is now cultivated for industrial starch production.

None of the viruses infecting cassava in Latin America is known to have been carried to either Africa or Asia, but over time, the crop became infected by indigenous viruses. The first report of a virus-like disease in African cassava was made in 1894 from what is now northeastern Tanzania. The original German descriptor, 'Krausellkrankheit', made reference to the characteristic mosaic symptoms elicited in affected plants. It was not until just over a decade later, however, that the first firm indication was given that the disease had a viral etiology. In spite of these early reports, there seems to have been little concern about the impact of cassava mosaic disease (CMD) until the 1920s. Between 1929 and 1937, however, numerous reports were made of the spread and damaging effect on cassava crops of CMD from diverse locations throughout the continent, from the island of Madagascar off the southeastern shores of the African mainland, to Sierra Leone in West Africa. These developments provided the stimulus for the earliest concerted efforts to develop approaches to controlling the viruses that caused this damaging crop disease. Although substantial progress was made in the development of cassava varieties that were resistant to cassava mosaic-causing viruses in the 1930s and 1940s, the viruses themselves remained poorly understood, and it was not until 1983 that the first definitive study confirming the viral etiology of CMD was published. Geminiate virions were shown to encapsidate a bipartite genome of single-stranded circular DNA, leading to the designation of these viruses as geminiviruses in the genus *Begomovirus*. In Asia, symptoms of cassava mosaic disease were first observed from southern India in the 1950s, and subsequently from Sri Lanka in the 1980s. Since 2015, the disease has spread more widely, affecting Cambodia and Vietnam in South-East Asia.

Virion Structure

The two single-stranded circular DNA molecules (DNA-A and DNA-B) of CMGs are encapsidated within a virion having a unique architecture composed of two incomplete icosahedral particles (hemcapsids) fused to form a twinned, geminate particle from a single type of capsid protein. For each icosahedral half, 55 CP chains assemble into 11 capsomers. The near-atomic resolution of the virion structure of ACMV has been resolved by cryo-electron microscopy to 4.2 Å revealing that alternating conformations of the N-terminus of the CP confer stability of the twinned particle and most probably mediate the interaction with the encapsidated DNA (Fig. 2). This was further confirmed by similar studies with Ageratum yellow vein virus, and resolution at an even higher level

Fig. 2 Structure of African cassava mosaic virus determined by cryoelectron microscopy. Courtesy of Katharina Hipp.

(3.3 Å) showed that three distinct conformations of CP form the capsid and arrange the hemcapsid interface. The proposed model for geminivirus capsid assembly and DNA binding suggests that genomic DNA is crucial for the formation of the capsids and for directing the assembly of the capsomers and the virus particle. The high resolution model of the ACMV virion structure has also shown the position of amino acid side chains implicated in *B. tabaci* transmission of begomoviruses. The most critical, Q130 and N131, are located on the particle surface and are accessible to interact with vector insect receptors while other residues may influence particle stability and thus have indirect effects on virus transmission.

Genome

The eight genes on the DNA-A and DNA-B genome components are located in sense and complementary sense orientations on the circular covalently-closed single-stranded DNA molecules (Fig. 3). A conserved intergenic region (IR) of ca. 200 bp is shared between both genome components. This unique IR identifies DNA-B to be transreplicated by its cognate DNA-A only. Embedded in the IR is a stem loop comprising the TAATATTAC sequence that is highly conserved among almost all geminiviruses and which represents the origin of replication. While DNA-A can infect and replicate autonomously in a host plant it requires DNA-B for movement and systemic infection of the host. CMG genes are multifunctional and proteins are responsible for encapsidation and for directing the host machinery to provide cellular functions favorable for replication. In virion sense orientation on DNA-A, the structural protein gene CP (AV1) codes for the capsid protein, which is involved in whitefly transmission and transport, and which interacts with host proteins and binds to ss and double-stranded (ds)DNA. A functional CP, however, is not required for infectivity and movement. Thus, DNA-A with a defective or missing CP is still infectious and capable of systemic movement within its host, however its capacity for vector transmission is compromised. Upstream of CP, the AV2 gene also provides movement function. On the complementary-sense strand, the replication initiation protein Rep (AC1) initiates specific steps in DNA replication; TrAP (transcriptional activator protein)(AC2) and REn (replication enhancer protein)(AC3) further downstream of Rep, function as suppressors of post-transcriptional gene silencing (PTGS) and support efficient DNA replication respectively. AC4 is nested within Rep and involved in symptom expression and possibly in counter-defense. Genes on DNA-B enable virus movement within the cell and nucleus (nuclear shuttle protein, NSP)(BV1) as well as sustaining long distance spread and movement within the plant (movement protein, MP)(BC1).

Replication

Geminiviruses replicate in the nuclei of infected cells and depend on host DNA and RNA polymerases for their replication and transcription. Geminiviruses predominantly replicate in the phloem companion and parenchyma cells and some geminiviruses can also invade *mesophyll* cells but are never found in meristems. Thus, geminiviruses replicate in differentiated cells. Using host proteins the ssDNA genome is replicated by rolling circle- and recombination-mediated mechanisms in which double-stranded DNA intermediates are formed that are chromatinized with host histone proteins to form viral minichromosomes inside the nucleus. Rep recruits host factors, binds specifically to iteron sequences within IR and creates a nick in the conserved nonanucleotide TAATATTAC to initiate DNA replication. Rep also binds to a plant homolog of retinoblastoma protein to catalyze a series of intracellular reactions that move the cell from G to S phase to mobilize host factors essential for DNA replication. Double-stranded DNA (dsDNA) produced in the replication process then assembles under the control of TrAP and REn into

Fig. 3 Genome organization of bipartite cassava mosaic viruses. The proteins encoded by the components are indicated as follows: DNA-A component on the sense orientation encodes for the following proteins: CP or AV1; the coat protein, and the AV2 protein; and on the antisense orientation: Rep or AC1; replication associated protein, TrAP or AC2; the transcriptional activator protein, REn or AC3; the replication enhancer protein, and the AC4 protein. The DNA-B component encodes for the following proteins: NSP or BV1; the nuclear shuttle protein on the sense orientation and MP or BC1; the movement protein on the antisense orientation. The conserved region (CR) is the common region between the DNA-A and DNA-B components. For each component the conserved hairpin structure, containing the nonanucleotide sequence TAATATTAC within the loop structure, is shown at position zero.

transcriptionally active mini-chromosomes. The nuclear export is mediated by NSP, from nucleus to the cytoplasm, and movement out of the cell through plasmodesmata and long distance transport and systemic movement are facilitated by MP.

Transmission

CMGs, in common with all other members of the genus *Begomovirus*, are transmitted by the whitefly vector *B. tabaci*. Transmission can also be achieved through grafting, and relatively inefficiently through mechanical inoculation of indicator plants, but there is no seed-borne transmission. Cassava is normally propagated through the use of vegetative cuttings, and this is perhaps the most frequent source of infection in new crops under field conditions. *Bemisia tabaci* adults feed, mate, and reproduce preferentially on the upper newly-emerged leaves of cassava plants, and almost all transmission occurs here. Transmission is persistent, and ACMV has been shown to be retained by *B. tabaci* adults for up to 9 days. Transtadial, but not transovarial transmission, has been demonstrated, although the larval instars are unimportant in the epidemiology of CMGs in view of their sessile nature. Minimum periods for each of the stages of transmission for ACMV by *B. tabaci* adults are: acquisition (3 h), latent period (3 h), and inoculation (10 min). Inoculated plants begin to show symptoms of infection after 3–5 weeks. Varying levels of transmission efficiency have been reported, ranging from 0.3% to 10%, depending primarily on the nature of the CMG infection in the plants from which virus is acquired. There is evidence for a limited degree of co-evolutionary adaptation between the whitefly vector and CMGs, as Indian whiteflies are significantly better at vectoring Indian than African CMGs and vice versa. However, within Africa, there is currently no indication that whiteflies from a particular location are more efficient at vectoring locally-occurring CMGs than they are at vectoring CMGs from another part of the continent. There is, however, an important balance between the pattern of transmission and the nature of the virus infection. More severe infections, caused either by more virulent virus species/strains or by mixed virus infections, lead to a greater frequency of whitefly-borne infection but diminished propagation through cuttings by farmers. Conversely, more moderate or mild infections, caused by less virulent virus species/strains occurring in single infections, lead to less frequent whitefly-borne infection and increased propagation through cuttings by farmers. This balance dictates the epidemiological characteristics of CMG infection in any given location, area, or region.

Pathogenesis and Symptoms

Following initial infection of a previously uninfected cassava plant by a CMG, viral DNA moves through the phloem to the newly developing phloem and parenchyma cells immediately behind the meristem where rapid multiplication of virus particles takes place. Plants have developed defense responses to virus multiplication through the process of PTGS, but in response, CMG species/strains have developed various effective mechanisms to overcome this, and the degree of this effectiveness seems to be the main factor in determining the severity of disease resulting from infection. Both AC2 and AC4 have been shown to act as suppressors of PTGS. Significantly, in mixed ACMV + EACMV-like virus infections, the responses of the two viruses to host plant PTGS are complementary, leading to a synergistic interaction between the two viruses, greatly increased titers of both, and a concomitant increase in severity of the disease symptoms expressed in the plant. Molecular studies of these interactions have shown that the abundance of short interfering RNA (siRNA) molecules associated with the host plant PTGS response increases over time in pure ACMV infections, yet remains low over similar time periods for ACMV + EACMV-UG co-infections. Synergism has been described for ACMV + EACMCV mixtures in Cameroon, but its significance is greatest in the widely occurring ACMV + EACMV-UG mixed infections that cause severe CMD in many parts of East and Central Africa.

As CMG virions replicate in infected cells, chloroplasts become distorted and reduced in number leading to the appearance of a patchy mosaic of chlorotic leaf portions interspersed with normal green leaf tissue. The chlorotic mosaic patches have discrete, non-diffuse borders, but these may vary greatly in size, ranging from small portions of individual leaflets to the entire leaf (Fig. 4). In moderate to severe infections, leaves are distorted and reduced in size and the growth of the plant is stunted. The severity of symptoms is affected by several factors, including the virulence of the CMG strain, the occurrence of mixed virus infection, temperature, host susceptibility and the stage of growth of the plant. Varieties display a full range of responses to CMG infection, ranging from near immunity to extreme sensitivity resulting in plant death. The most frequent cause of severe symptoms is where ACMV and EACMV (or related viruses) occur in mixed infection. This is a consequence of the synergistic interaction between these viruses which leads to increased virus titer of both. There are currently no anecdotal or published records of synergistic interactions between ICMV and SLCMV in South Asia.

Plants infected through the cutting typically express symptoms in the first-formed leaves immediately on sprouting. Plants that sprouted without virus infection, but which were subsequently infected by the whitefly vector express symptoms only in leaves above the point of infection, although there is a latent period of 3–5 weeks between inoculation and the appearance of symptoms. These contrasting patterns of symptom expression make it possible to distinguish plants infected through the cutting from those infected during crop growth by the whitefly vector. Separating these two infection types has become an important facet of field research into the epidemiology of CMGs. Symptoms of CMD caused by ICMV and/or SLCMV in Asia vary in severity, depending on the factors described above, but the characteristics of the symptoms are the same as those of African CMD, as is the distinction between cutting-borne and whitefly-borne infection.

Fig. 4 Cassava mosaic disease (CMD) symptoms: (A) & (B) – Sri Lankan cassava mosaic virus in Vietnam; (C) – African cassava mosaic virus in Gabon; (D) – mixed infection of African cassava mosaic virus and East African cassava mosaic virus-Uganda in Burundi.

There are currently no reported cases of cassava varieties with immunity to infection by CMGs. However, there are many varieties that are highly resistant, and when these are infected, symptoms expressed are often confined to small portions of a few leaves. A common feature of resistant varieties is symptom recovery, as lower symptomatic leaves drop naturally and new foliage is asymptomatic. This phenomenon is linked to reversion, which is the absence of virus in a proportion of cuttings taken from an infected parent plant. This is thought to be a consequence of the incomplete systemicity of CMGs in resistant varieties.

Epidemiology

Diversity and Distribution

Distribution of the African CMGs

The earliest studies of CMG diversity and distribution used serological techniques to characterize variability, and then utilized that variability to develop diagnostic tests based on the use of monoclonal antibodies in the enzyme-linked immunosorbent assay (ELISA). Using these methods, two principal groups of CMGs were recognized that were subsequently confirmed as distinct species following the sequencing of DNA-A molecules. These were ACMV and EACMV. The earliest distribution maps of the African CMGs showed EACMV to occur in the coastal east African areas of Kenya, Tanzania, and Madagascar, as well as Malawi and Zimbabwe. ACMV, by contrast, occurred throughout the remainder of the cassava-growing areas of Africa, from South Africa and Mozambique in the southeast, to Senegal in the northwest. Significantly, at this time there was no reported zone of co-occurrence of the two virus species. With the increased use of polymerase chain reaction (PCR)-based diagnostics from 1990s onward, it became possible to identify differences not solely associated with the coat protein. This led to two important developments in the understanding of CMGs in Africa. First, several new species were identified, most of which were more closely related to EACMV than to ACMV. Second, it was shown that virus mixtures belonging to different species occurred frequently. A notable consequence of this finding was the concomitant evidence for the more widespread distribution of the EACMV-like viruses than had hitherto been recognized. New virus identifications included: SACMV (1998), EACMMV (1998), EACMCV (2000), EACMZV (2004), EACMKV (2006), ACMBFV (2012), and CMMGV (2012). Significantly, all but one (ACMBFV) of the CMGs occur in different parts of East and Southern Africa, while ACMV predominates in West Africa (**Fig. 5**). EACMCV, the only EACMV-like virus occurring in West Africa, is less frequent and often occurs in mixed infections together with ACMV. ACMV is absent from coastal areas of Kenya and

Fig. 5 Distribution of cassava mosaic geminiviruses in Africa: ACMV (African cassava mosaic virus); ACMBFV (African cassava mosaic Burkina Faso virus); EACMV (East African cassava mosaic virus); EACMV-UG (East African cassava mosaic virus-Uganda); EACMCV (East African cassava mosaic Cameroon virus); EACMZV (East African cassava mosaic Zanzibar virus); EACMMV (East African cassava mosaic Malawi virus); EACMKV (East African cassava mosaic Kenya virus); SACMV (South African cassava mosaic virus); CMMGV (Cassava mosaic Madagascar virus).

Tanzania. Since there has been very little CMG characterization in many of the cassava-growing countries of Africa, it seems likely that further variability within this group of viruses still remains to be revealed. An assessment of the data currently available has led to the conclusion that East Africa is the center of diversity for the EACMV-like CMGs and is probably the home for yet-to-be-identified wild hosts of the proto-CMGs that were first introduced to cassava by *B. tabaci* sometime between the earliest introductions of cassava to this part of Africa in the eighteenth century, and the first report of CMD in 1894.

Distribution of CMGs in Asia

ICMV and SLCMV are considered to be native to South Asia and have been recorded from cassava-producing areas of India and Sri Lanka for several decades. Early serology-based work identified ICMV from southern India. However, following the characterization of SLCMV as the causal agent of CMD in Sri Lanka in 2002, subsequent surveys in India showed that SLCMV was more widely distributed there than ICMV. The CMGs in India have been identified from Kerala, Karnataka, Tamil Nadu, Andhra Pradesh, Madhya Pradesh, and West Bengal states, a zone covering all of the major cassava-producing parts of the country. Although it has been suggested that SLCMV is a more aggressive virus than ICMV, and has been expanding its geographical coverage, the absence of systematic surveys conducted over several years means that the evidence for this remains circumstantial.

CMD was reported for the first time from Southeast Asia (SE Asia) from a single location in Ratanakiri Province in Northeastern Cambodia in 2015. The causal virus was SLCMV, and it was assumed that this new outbreak had arisen through the introduction of infected planting material from South Asia. Since that time there has been rapid spread of CMD and associated SLCMV through most of the major cassava-producing areas of Cambodia, as well as southern Vietnam. An isolated report of the disease from Ha Tinh Province in northern Vietnam presents a risk for spread to neighboring Laos, and there are also several reports of CMD in Thailand that have yet to be officially confirmed. The most recent confirmed reports of the occurrence of CMD in Asia come from the southern Chinese regions of Hainan and Fujian, in both cases coupled with positive diagnoses of SLCMV. Rapid spread of SLCMV through SE Asia is thought to be driven by extensive cross-border and intra-regional commercial trade in cassava stems, although there is also clear evidence of local spread through whitefly transmission. The progress of the SE Asian pandemic has also been exacerbated by the extreme susceptibility to CMG infection of virtually all of the cassava varieties currently being cultivated. Given the rapid spread of CMD through this region from 2015 to 2019, it seems likely that new occurrences will be reported from

Laos, Thailand and Myanmar in the near future, and there is also a greatly increased threat to other major-cassava producing countries in the region – Philippines and Indonesia.

Recombination and the CMD pandemic

The CMGs represent a very dynamic group of viruses, and evidence has been presented for the occurrence of both pseudo-recombinants, in which the DNA-A of one virus species co-replicates with the DNA-B of another species, as well as true recombinants, in which portions of the DNA-A or -B of one species have been spliced into the DNA-A or -B of another. In fact, all of the EACMV-like viruses other than EACMV show evidence for recombination events either with known or as yet unknown begomoviruses. One of the most important developments in the study of CMGs in Africa was the recognition that an unusually damaging strain, referred to as EACMV-UG, had arisen through a recombination event between EACMV and ACMV in which a 340 nt portion of ACMV AV1, had replaced the equivalent portion of the DNA-A of EACMV. The consequence of this was that ELISA-based diagnostic tests erroneously identified this strain as ACMV. This is one of the reasons why PCR-based diagnostic methods are now used almost exclusively for CMG monitoring work. EACMV-UG was associated with the rapid epidemic-like spread of CMD in East and Central Africa through the latter part of the twentieth and early 21st century. Countries affected by the severe CMD pandemic included: Angola, Burundi, Cameroon, Central African Republic, Democratic Republic of Congo (DRC), Gabon, Kenya, Republic of Congo, Rwanda, South Sudan, Tanzania, and Uganda. Localized identifications of EACMV-UG have also been made from Burkina Faso, Chad, Equatorial Guinea, South Africa, Swaziland, and Zimbabwe. The dynamic character of CMG diversity and distribution cannot be over-emphasized, and the propensity that this group of viruses shows to produce both naturally occurring pseudo-recombinants, as well as novel true recombinants, ensures that the patterns of diversity and distribution will continue to evolve. It is significant to note, however, that most of the CMG variability occurs amongst the EACMV-like viruses, which show a high propensity for recombination. This contrasts strongly with ACMV, for which all 311 publicly-available accessions have > 94% homology and can be considered to be a single strain of the same species.

Field-Level Epidemiology

Epidemiological studies of the CMGs can be broadly categorized into two groups: those that describe patterns of infection at the field level and those that relate to area or region-wide spread. In the case of the former, external sources of infection have been shown to be most important for determining the rate and quantity of infection in initially CMD-free plantings in the normal field environment. Gradients of infection occur in which new infections are most frequent on the windward sides of cassava crops and these gradients are matched by similar patterns of vector distribution. Multiple regression relationships have been used to describe the association between measures of inoculum pressure and final CMD incidence in test plots. Gompertz curves model patterns of infection increase in plots of CMG-susceptible cassava cultivars, and incidence increases rapidly to 100% over the first 3–6 months of growth. For resistant varieties, however, under similar conditions of inoculum pressure, rates of infection increase are much lower and final incidences typically range from 0% to 50%. Mathematical models have been generated that predict patterns of CMD spread under varied conditions of virus infection and vector abundance. The great majority of epidemiological research has focused on CMD in Africa, although several studies in India have confirmed that patterns of cutting-borne and vector-borne spread of CMGs are largely the same as those observed in Africa.

Regional Epidemiology

Following the earliest ‘first colonization’ descriptions of African CMD epidemics in the 1920s and 1930s, a few reports were made of rapid area-wide spread of severe CMD at other times during the twentieth century, some of the most notable of which were epidemics in Cape Verde and south-eastern Nigeria in the 1990s. Of much greater importance, however, has been the African CMD pandemic that was first reported from the northern-central part of Uganda in the late 1980s. CMD associated with the epidemic was unusually severe and was rapidly spread by super-abundant populations of *B. tabaci*. During the 1990s it became apparent that the zone affected by this severe CMD was expanding southwards at a rate of 20–30 km per year, and in 1997 molecular studies revealed that the severe disease phenotype was associated with the occurrence and spread of an ‘invasive’ recombinant CMG, EACMV-UG, commonly in mixed infection with the locally occurring, but now synergized ACMV. Regular monitoring surveys conducted throughout the East and Central African region through the 1990s and early part of the 21st century have used PCR-based diagnostics to map the spread of the EACMV-UG associated with this ‘pandemic’ of severe CMD. This work has given rise to first reports of EACMV-UG and resulting severe CMD in ten additional countries in East and Central Africa: Kenya (1996), South Sudan (1997), Tanzania (1999), DRC (1999), Republic of Congo (1999), Rwanda (2001), Burundi (2003), Gabon (2003), Angola (2008), and Cameroon (2010). Significantly, the pandemic ‘front’ advanced through north-western Tanzania from the Uganda border a distance of c. 400 km between 1999 and 2004. Although the severe CMD pandemic threatened to spread further through southern Africa and westwards to Nigeria, the period post-2010 saw a decline in new reports of spread. Evidence from Uganda in 2019 indicates that EACMV-UG has now largely been replaced by ACMV, although the reasons for this pattern of change are currently unclear. An important contributing factor to this amelioration in the CMD pandemic in Africa is likely to be the increasingly widespread adoption by farmers of CMD-resistant varieties.

Diagnosis

CMD symptoms are very characteristic, although they cannot be used to discriminate between the CMG virus species causing the infection. Additionally, symptoms are almost always expressed in infected plants at some stage during their period of growth, which means that symptoms are widely used as an indication of infection during surveillance activities and by regulatory authorities during certification inspections. The characteristic mosaic pattern of CMD symptoms has also made it possible to use machine learning and artificial intelligence to develop a smartphone app – Nuru AI – which allows untrained users to recognize CMD with a high degree of accuracy. Laboratory-based methods are required, however, to increase the accuracy of detection as well as to identify the various CMG species.

ELISA was the first of these approaches to be widely applied to CMG detection. Monoclonal antibodies allowed a distinction to be made between ACMV, EACMV, and ICMV, at a time when only these three species were recognized. The emergence of the severe CMD epidemic in Uganda, however, highlighted the weakness with this serology-based method, as EACMV-UG was misdiagnosed as ACMV by ELISA, since EACMV-UG was a recombinant virus with the coat protein of ACMV. From the late 1990s onwards PCR was used almost exclusively for the detection and identification of CMG species. PCR presents an easy and robust detection system for CMGs and specific primer sets and a diverse array of PCR protocols are available to achieve reliable detection of these viruses in cassava. To verify specificity, sequencing of PCR amplicons confirms virus identity. However, because of recombination at various positions across DNA-A, amplification of genome fragments may not fully resolve the diversity of DNA-A and the association of sequence to a particular virus species. Hence amplification followed by sequencing of the entire DNA-A genome component is required for reliable virus identification. This is achieved by using inverse, abutting PCR primers located in a conserved region of DNA-A (CP) to amplify the entire circular DNA-A molecule. A more general approach is rolling-circle amplification (RCA) using phi29 (Φ 29) DNA polymerase. Plant DNA including the circular virus DNA is amplified in an isothermal process using random oligonucleotide primers. Phi29 polymerase is highly processive and in this unique RCA process, small circular DNA molecules are replicated nearly infinitely. By enzymatic restriction of the RCA products using rarely-cutting restriction enzymes, CMG DNA fragments or complete virus genome components can be resolved and the entire begomovirus composition of a plant sample can be analyzed without prior knowledge of virus sequences. With this approach it is possible to detect unexpected and unknown begomoviruses, mixed infections and satellites. Sample preparation and DNA extraction are identical to other methods and commercial kits are available. RCA generates genome DNA sequences as concatemers. Virus identification can then be performed after restriction digestion, cloning and sequence analysis.

Economic Importance

CMD symptoms of leaf chlorosis, reduction of leaf size and plant stunting lead to a reduction in the quantity of photosynthetic assimilates channeled into the tuberous roots, and through this, a reduction in yield. The degree of yield loss varies greatly, depending primarily on the susceptibility of the cassava cultivar, the virulence of the CMG species/strain, and the stage of growth at which infection occurred (being most severe for cutting-infected plants). Typically, individual plants sustain yield losses ranging from 20% to 100%. The only study of the effects of specific viruses on yield showed average yield losses to be 42% for ACMV alone, 12% for EACMV-UG mild, 68% for EACMV-UG severe, and 82% for mixed ACMV + EACMV-UG. The relatively moderate losses attributable to ACMV infection, coupled with moderate to low incidences, have been the reasons for the apparent lack of concern through large parts of cassava-growing Africa about the impact of CMGs and CMD. This outlook changed markedly, however, following the emergence and regional spread of the CMD pandemic. Extensive surveys of CMD incidence, CMD severity, and the occurrence of the causal viruses have made it possible to make continent-wide yield loss estimates for CMD. The last of these (2006) provided estimates for losses in pandemic-recovered (16% loss), pandemic-affected (47%), and as yet unaffected (18%) countries in sub-Saharan Africa, leading to an overall loss figure of 34 million tons per year, which was equivalent to roughly a third of total African production of fresh cassava roots. Following the region-wide spread of the pandemic, major control programs were implemented, and anecdotal evidence suggests that this has resulted in reductions in CMD incidence and reduced losses. This declining impact of the disease in Africa is likely to be the reason why there have been no comprehensive assessments of losses since 2006.

For CMD in India, losses of up to 84% have been recorded at field level, although these are said to vary, as in Africa, depending on the varietal response, type of infection and virus species/species mixture causing the infection. There are currently no published records of overall losses due to CMD in South Asia or for the more recently affected countries of Southeast Asia.

Control

The most widely practiced approaches to controlling the CMGs that cause CMD include the deployment of host plant resistance and the use of cultural methods, particularly phytosanitation. More recently, considerable attention has been directed toward the use of genetic engineering techniques to produce transgenic virus-resistant cassava plants.

Host Plant Resistance

The potential value of introgressing virus resistance genes from wild relatives of cassava was recognized from the earliest days of CMD research in the 1920s/1930s, and inter-specific crosses combining cultivated cassava with Ceara rubber (*Manihot glaziovii*) were developed independently through breeding programs in modern-day Tanzania and Madagascar. F1 progeny were triple backcrossed with cultivated cassava to produce plants that combined acceptable food quality with significantly enhanced resistance to CMGs. Germplasm developed in this way formed the basis for the later continental breeding program run from the Nigeria-based International Institute of Tropical Agriculture (IITA), which from its establishment in 1967, to the present day, has developed thousands of CMD-resistant cassava clones. Many of these have been sent to cassava-producing countries in Africa for use either specifically for CMD management programs, or more generally for cassava development. Germplasm derived from the initial interspecific crosses uses the name prefix 'TMS' for 'Tropical Manihot species'. This resistance source is multigenic and has provided high levels of resistance which have been very durable when used against all CMGs and CMG combinations. Four distinct mechanisms of resistance are recognized: resistance to infection, resistance to virus multiplication, resistance to virus movement (leading to incomplete systemicity), and resistance of normal plant function to the effects of virus infection. During the 1990s, resistant landraces from West Africa, given the name prefix 'TME' for 'Tropical Manihot esculenta', were incorporated into the breeding program. These have been shown to possess alternative sources of resistance, one of the most important of which has been characterized through genetic analyses as a single dominant gene designated CMD2. Molecular marker approaches have been used subsequently to combine the multigenic *M. glaziovii*-derived resistance with CMD2. In recent years, improvements in sequencing technologies have enabled researchers to undertake genome-wide association studies. These have been used to identify major QTLs associated with CMD resistance and they have provided new tools to improve the efficiency of the breeding process.

Hundreds of CMG-resistant varieties have been released and disseminated throughout the cassava-growing areas of sub-Saharan Africa. However, their adoption by farming communities has been most widespread in CMD pandemic-affected countries, where they have provided the only effective means of restoring cassava production to pre-pandemic levels. In South Asia, sources of resistance have been drawn from the breeding work undertaken in Africa. Evaluations of seedling populations obtained from introduced germplasm have led to the development of varieties such as CMR1, CMR129, CR21-10, and CR43-11 which combine high starch content with strong resistance to ICMV and SLCMV. Some of this germplasm, together with other CMD-resistant varieties from IITA in Nigeria are currently being introduced to Southeast Asia as part of regional efforts to control the CMD outbreak there.

Cultural Methods

A range of cultural methods has been proposed for the control of CMGs. The methods most widely recommended have been the removal of infected plants (roguing) or the selection of disease-free planting material for the establishment of a new crop (selection). Crop isolation, adjusting crop disposition in relation to the prevailing wind, varying planting date, varietal mixtures, and intercropping cassava with other 'putative' protective crops have all been suggested at various times as potentially useful control options for CMGs. No convincing experimental evidence has yet been presented to confirm the value of any of these methods, however, and current field practice is restricted to selection and occasional roguing. Roguing is considered to be of value within the framework of institutional programs for the multiplication of CMD-resistant germplasm, in view of the requirement for the production of high-quality planting material. Experiments conducted in 'post-epidemic' areas of East Africa, first affected by the CMD pandemic five or more years previously, have provided clear evidence for the value of selection of CMD-free stems when choosing planting material. Local cultivars treated in this way provided equivalent yields to those of CMD-resistant varieties after two cropping cycles. A key drawback to the wider adoption of this approach, however, is the variability in effectiveness of the approach in relation both to the virus inoculum pressure of the location, as well as the relative susceptibility of the cultivar.

Systems for the phytosanitary control of CMGs have been greatly strengthened in several parts of Africa in recent years. Most notably, certification guidelines for cassava have been developed and appended to Seed Acts in countries such as Nigeria, Rwanda and Tanzania. These guidelines include maximum tolerance levels for CMD incidence. This has facilitated the certification of early generation cassava 'seed' (= planting material) and promoted the production of near virus-free planting material. The approach is helping to ensure that newly developed virus-resistant varieties are multiplied and disseminated in a healthy condition and it is reducing overall incidences of CMD.

Virus Resistance by Engineering

Engineering virus resistance by expression of virus sequences in transgenic plants is a strategy that is also used to achieve resistance against geminiviruses. The most common approach is to engineer RNAi (RNA interference) constructs as inverted-repeats of virus sequence which are spaced by an intron. Splicing of the intron upon transcription generates a "hairpin" dsRNA that is targeted by the plants RNA silencing machinery. RNAi triggered antiviral defense using constructs comprising Rep sequences is effective against Tomato yellow leaf curl virus (TYLCV) and against Bean golden mosaic virus (BGMV). The stability of this resistance was verified in field trials showing virus resistance under field conditions for several seasons and the feasibility of the

approach to provide protection in both crops. In Brazil, transgenic common beans resistant to BGMV were released in 2011 as a commercial variety. Thus RNAi strategies may protect plants against DNA viruses as shown also for other crops including cotton as well as cassava, by boosting the antiviral defense. The effectiveness of the RNAi protection depends on the choice of the viral sequence and the abundance of small interfering RNAs generated from the hairpin RNA transgene. In addition, temperature and the intrinsic interaction of virus and plant host influence the effectiveness of silencing and the level of resistance achieved. RNAi strategies have been used to induce gene silencing against cassava infecting geminiviruses. In all approaches, symptoms were attenuated and virus DNA accumulation was drastically reduced. Broad spectrum resistance against several CMGs e.g., ACMV, EACMCV, and SLCMV can be achieved when there is sufficient sequence homology between the siRNAs and transcripts of the viruses.

Several studies have shown the effectiveness of CRISPR-Cas9 to engineer resistance against the geminiviruses Tomato yellow leaf curl virus (TYLCV) and Beet curly top virus (BCTV). A single-guide RNA (sgRNA) carrying the TAATATTAC nonanucleotide origin of replication of geminiviruses was used to induce a broad spectrum virus resistance. In cassava, CRISPR-Cas9 was used to engineer resistance to ACMV targeting AC2 and AC3 with a single sgRNA. However, CRISPR-Cas9 did not show any difference to the wild-type susceptible plants because of the emergence of a cleavage mutant of ACMV in transgenic plants. The selection of cleavage resistant mutants, as shown for ACMV, or new virus mutants that evade the sequence-specific action of transgene derived RNAi in TYLCV transgenic plants or ACMV transgenic cassava demonstrate the challenges of any of the engineering strategies employing targeting sequences of a replicating virus. However, this can be addressed by using multiplexed CRISPR/Cas9 with multiple sgRNAs to target virus complexes, as shown for the control of Cotton leaf curl virus (CLCuV). With more information on functional networks and genes involved in vital virus functions, CRISPR-Cas9, RNAi or similar approaches will be increasingly used for the editing or interfering with expression of host genes to achieve virus resistance in cassava.

Biosafety considerations

Cassava plants transformed for resistance to CMGs have been tested under field conditions in several African countries (Kenya, Nigeria, Uganda) through confined field trial arrangements, with promising results confirming the effectiveness of the strategy. However, uncertainty in most African countries about the consequences of the widespread cultivation of GMOs has slowed the adoption of biosafety guidelines and meant that at the time of writing (2019) there are no transgenic cassava plants that have been evaluated under 'real-world' conditions in farmers' fields. In January 2019, however, the National Biosafety Management Agency of Nigeria made its first approval of a GM crop – podborer-resistant cowpea. Since Nigeria is the world's largest producer of cassava, and since its cassava crop is widely affected by CMD, this development offers significant promise for the future release of GM CMD-resistant cassava varieties. Furthermore, this is a move that could provide a signal for other countries similarly affected by cassava viruses to follow suit. Given the huge impact that CMD has on the production of one of the world's most important staple food crops, the widespread adoption of science-based strategies to control may be essential if the food security of hundreds of millions of cassava-dependent households in Africa and elsewhere is to be assured.

Glossary

Agro-inoculation An inoculation technique in which *Agrobacterium tumefaciens* is used to deliver a full-length infectious clone of a virus into a plant cell.

Plasmodesmata A narrow channel of cytoplasm that functions as a bridge between two plant cells to facilitate movement of macromolecules.

Reverse transcriptase An enzyme that utilizes an RNA template for synthesis of DNA.

Ribosome shunt A translational mechanism in which ribosomes enter the RNA at the 5' end and scan for a short distance before being translocated to a downstream point.

Semi-persistent transmission Vector acquires the virus in minutes to hours, and can transmit to other plants for hours after the initial feeding.

Transgene A gene introduced into an organism through any one of a number of genetic engineering techniques.

Introduction

The members of the family *Caulimoviridae* are plant viruses that replicate by reverse transcription of an RNA intermediate and whose virions contain circular, double stranded DNA. They belong to the order *Ortervirales*, a virus order that encompasses five families of reverse transcribing viruses. Although caulimoviruses replicate by reverse transcription, integration into host chromosomes is not required for completion of their replication cycle. The circular DNA encapsidated in virions is not covalently closed, as it contains at least one discontinuity in each DNA strand, and these discontinuities occur as a consequence of the replication strategy of the virus. There are eight genera in this family and they can be divided into two groups based on virion morphology; the members of the genera *Caulimovirus*, *Petuvirus*, *Cavemovirus*, *Rosadnavirus*, *Solendovirus*, and *Soymovirus* contain viruses that form icosahedral particles that are largely found within amorphous inclusion bodies in the cell (**Fig. 1(A)** and **(B)**).

In contrast, the members of the genera *Badnavirus* and *Tungrovirus* form bacilliform particles that are not associated with inclusion bodies (**Fig. 1(C)**). Their virions are found in the cytoplasm either individually or clustered in palisade-like arrays.

Cauliflower mosaic virus (CaMV), the type species of the genus *Caulimovirus*, was the first of the plant viruses to be shown to contain double-stranded DNA (dsDNA) in its icosahedral virion in 1968. This discovery led to an extended investigation into its replication strategy throughout the 70's and early 80's, culminating in 1983 when it was shown that CaMV replicated through reverse transcription of an RNA intermediate. Perhaps because the genome of CaMV is composed of dsDNA, it was also the first of the plant viruses to be completely sequenced and cloned into bacterial plasmids in an infectious form.

In the early 1980s, CaMV was thought to have some promise as a vector for foreign genes in plants. However, the effort to convert CaMV into a vector was scaled back when it was shown that the virus genome could tolerate only small insertions of up to a few hundred base pairs of DNA. A few small genes, such as dihydrofolate reductase and interferon, were eventually expressed in plants via a CaMV vector, but other viruses have been shown to be much more versatile as vectors for foreign genes. Although the caulimoviruses have had only limited utility as plant virus vectors, they continue to have a great impact on plant biotechnology. The 35S promoter of CaMV is capable of directing a high level of transcription in most types of plant tissues. This promoter was used to drive expression of one of the first transgenes introduced into transgenic plants, and it is still widely used for expression of transgenes for both research and commercial applications. The promoter regions of several other caulimoviruses have also been evaluated for expression of transgenes in both monocots and dicots, and they can be good alternatives to the CaMV 35S promoter.

Fig. 1 Inclusion bodies and virions of members of the family *Caulimoviridae*. (A). Amorphous inclusion body of CaMV (I) adjacent to a chloroplast (Chl). Individual virions can be seen in the vacuolated regions of the inclusion body. (B). Icosahedral virions of CaMV visualized within an inclusion body. (C). Purified bacilliform virions of CoYMV. CoYMV photo courtesy of Ben Lockhart (University of Minnesota).

For many years, only plant viruses that had icosahedral virions of 50 nm in diameter were thought to have genomes composed of dsDNA. However in 1990, it was shown that the bacilliform virions of Commelina yellow mottle virus (CoYMV) contained circular, dsDNA, and *Commelina yellow mottle virus* became the type species for the genus *Badnavirus*. Nucleic acid isolated from the bacilliform virions was resistant to RNase and degraded by DNase. Furthermore, DNA treated with S1 nuclease revealed that the CoYMV genome contained at least two single-stranded discontinuities, a hallmark of the plant viruses that replicate by reverse transcription. In addition to CoYMV, DNA purified from Banana streak virus (BSV), Kalanchoe top-spotting virus (KTSV) and Canna yellow mottle virus, providing evidence that they should also be placed in the new genus *Badnavirus*. Currently, there are 57 species in the *Badnavirus* genus (Table 1), many of which cause economically important diseases in the tropics.

Soon after the discovery that CoYMV was a DNA virus, the bacilliform component of rice tungro disease was also shown to contain circular, dsDNA. Rice tungro is the most important virus disease of rice in South and Southeast Asia, with annual losses approaching \$1.5 billion dollars. The disease is caused by a complex of an RNA virus, called Rice tungro spherical virus (RTSV) coupled with the bacilliform dsDNA virus called Rice tungro bacilliform virus (RTBV). The genus *Tungrovirus* is distinguished from the genus *Badnavirus* because RTBV has one more open reading frame (ORF) than CoYMV and overall, the RTBV genome has only 20%–25% nt sequence identity with members of the genus *Badnavirus*. There is only one species in the genus *Tungrovirus*, although several isolates of the species *Rice tungro bacilliform virus* have been collected and sequenced.

Taxonomy, Phylogeny, and Evolution

The family *Caulimoviridae* consists of eight genera (Table 1), and they can be conveniently divided into two groups based on virion morphology. Viruses with icosahedral virions (Fig. 1(B)) include the genera *Caulimovirus*, *Petuvirus*, *Soymovirus*, *Rosadnavirus*, *Solendovirus*, and *Cavemovirus*. Viruses with bacilliform virions (Fig. 1(C)) include the genera *Badnavirus* and *Tungrovirus*. Genera can be further distinguished because of differences in genome organization (Fig. 2(A)) as well as phylogenetic analyses of proteins such as the reverse transcriptase, as illustrated in Fig. 2(B). All members of the family *Caulimoviridae* infect only plants. There are no animal or insect viruses in this family. Complete and partial nt sequences of members of the family *Caulimoviridae* are listed in Table 1. Only a single accession number is given for CaMV and RTBV, although multiple strains of each have been sequenced.

Virion Structure

The viruses in the genera *Caulimovirus*, *Cavemovirus*, *Soymovirus* and *Petuvirus* form non-enveloped, isometric particles that vary in size from 43 to 50 nm. The virion is composed of 420 subunits with a $T = 7$ structure. The viruses in the genera *Badnavirus* and *Tungrovirus* form non-enveloped, bacilliform particles that are 30 nm in width, but can vary in length from 60 to 900 nm. The length most commonly observed is 130 nm. Their structure is based on an icosahedron, in which the ends are formed from pentamers and the tubular section is made up of hexamers. The capsid also is loosely decorated with the 15 kDa virus-associated protein, which is encoded by ORF-III. The virions typically accumulate in amorphous inclusion bodies, which are composed primarily of a 62 kDa multifunctional protein encoded by ORF-VI. The virions of the family *Caulimoviridae* contain a single, circular dsDNA that is 7.2–9.3 kbp in length.

Genome Organization

Several genome features are common to all members of the family *Caulimoviridae*, in addition to their circular dsDNA genomes. For example, the dsDNA is not covalently closed; it has at least two discontinuities, but may have up to four. The most significant difference among the caulimoviruses concerns the arrangement and number of ORFs (Fig. 2). All of the ORFs are found on only one of the DNA strands and all of the viruses have at least one strong promoter that drives the expression of a terminally redundant mRNA. In addition, all of the viruses have a reverse transcriptase, and in most cases, it is located downstream from the coat protein (CP). Several active sites can be identified within the reverse transcriptase protein, including a protease, the core reverse transcriptase, and RNaseH activity. The reverse transcriptase of PVCV is distinguished from all other members of the family *Caulimoviridae* because it has the core features of an integrase function, in addition to other functions.

The genome organization of CaMV is the best characterized of the family and it is discussed in detail here. The CaMV genome is approximately 8000 bp in size and it contains three single-stranded discontinuities. One discontinuity occurs in the negative sense DNA strand and by convention, this is the origin of the DNA sequence. Two other discontinuities occur in the positive sense strand, one at nt position 1600 and a second at approximately nt position 4000. The virus genome consists of seven ORFs (Fig. 2(A)). ORF1 encodes a protein necessary for cell-to-cell movement (P1). ORFs 2 and 3 (proteins P2 and P3) are both required for aphid transmission. P3 also has an additional role in cell-to-cell movement. ORF4 encodes the CP, and ORF5 encodes a reverse transcriptase that also has protease and RNaseH domains. With the exception of *Petunia vein clearing virus* (PVCV), none of the reverse transcriptases of the caulimoviruses have evidence for an integrase function. The ORF6 product (P6) was originally described as the major inclusion body protein, but it also has a function as a translational transactivator (TAV). It physically interacts with host ribosomes to reprogram them for reinitiation of translation of the polycistronic 35S RNA. Furthermore, P6 is an important symptom and host range determinant. No protein product has been found for ORF7. Its nt sequence appears to play a regulatory role in aligning ribosomes for translation of other CaMV gene products.

Two transcripts are produced from the CaMV genomic DNA. The 19S RNA serves as the mRNA for P6, whereas the terminally redundant 35S RNA serves as a template for reverse transcription and as a polycistronic mRNA for ORFs 1–5. One feature common to many of the caulimoviruses is the ribosomal shunt mechanism of translation. The ribosomal shunt has undoubtedly evolved over time to compensate for the complexity and length of the leader sequence of the genomic RNA. In the case of CaMV, this leader sequence is approximately 600 bp in length and it contains up to nine short ORFs that vary in size from 9 to 102 nt. The complexity of the CaMV 35S RNA leader sequence is bypassed through the formation of a large stem-loop structure, which allows ribosomes to bypass most of the leader and to initiate translation at ORF7. CaMV utilizes several other strategies for expression of the 35S RNA, including splicing and reprogramming of host ribosomes by the TAV for re-initiation of translation.

Fig. 2 Genome structure and phylogeny of members of the family *Caulimoviridae*. (A). Genome structure of representative viruses of the eight genera that comprise the family *Caulimoviridae*. Open reading frames (ORFs) are indicated by boxes, and are identified according to the information in the GeneBank nucleotide accession. The ORFs common to all genera include a movement protein (yellow), a capsid protein (green), and a protease/reverse transcriptase (purple). ORFs unique to a virus or whose function remains unidentified are in gray. The slashes on either end of the diagram (/) indicate where the genome is circular. The first base of the nucleotide sequence deposited in GenBank is located on the left, and the size of the genome is located on the right. Virus genera including *Petuvirus*, *Cavemovirus*, *Tungrovirus*, and *Badnavirus* produce polyproteins, which are presented as a single ORF. (B). Evolutionary relationships of the members of the family *Caulimoviridae*, based on the amino acid sequences of the reverse transcriptases. The evolutionary history was inferred using the Neighbor-Joining method. The optimal tree with the sum of branch length = 3.32101427 is shown. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (500 replicates) are shown next to the branches. The evolutionary distances were computed using the p-distance method and are in the units of the number of amino acid differences per site. All ambiguous positions were removed for each sequence pair (pairwise deletion option). There was a total of 2020 positions in the final dataset. Evolutionary analyses were conducted in MEGA X. The outgroup for comparison is hepatitis B virus strain A (HBV-A).

Properties and Functions of CaMV Gene Products

Movement Protein (MP)

CaMV ORF-I encodes a 37 kDa protein dedicated to cell-to-cell movement. The CaMV movement protein (MP) dramatically reconfigures the host plasmodesma by removal of the desmotubule, leading to the formation of a tubule structure through which the virions move to adjacent cells. The MP is delivered to the plasma membrane through a vesicular transport pathway where it

makes its way to the plasmodesma. Excess MP is thought to be recycled back to the central vacuole. By contrast, the CaMV virion is thought to be delivered separately to the tubules by inclusion bodies formed from the P6 protein. Other plant viruses whose MPs are capable of forming tubules include the tospoviruses, comoviruses, nepoviruses and bromoviruses.

Aphid Transmission Factor (P2)

The product of ORF-II (or P2) is an 18 kDa protein that is required for transmission by aphids. P2 exists in cells in the form of inclusion bodies. When an aphid probes a leaf, this triggers the release of CaMV virions from the P6 inclusion bodies, the dissolution of the P2 inclusion bodies and the distribution of the P2 protein on host microtubules, where they come into contact with the virions. The N-terminus of the P2 protein is capable of binding to the aphid stylet, whereas the C-terminus of P2 binds to the CaMV P3 protein, which is located on the surface of virions. Consequently, CaMV virions are acquired by aphids through an association with the P2 and P3 proteins. Inactivation of the P2 protein abolishes aphid transmission but the mutant virus remains fully infectious through mechanical inoculation.

Virion-Associated Protein (P3)

The product of ORF-III, a 15 kDa virion-associated protein (P3) has key roles in both cell-to-cell movement and aphid transmission. P3 is found on the surface of virions and functions as a bridge between the virion and the MP and P2 proteins. The N-terminus of P3 binds to either to MP or to P2 to facilitate cell-to-cell movement or aphid transmission, respectively. Although P3 is located on the surface of virions, it is not uncommon for it to be released during purification of CaMV virions.

Capsid Protein (P4)

ORF-IV encodes the main capsid component (P4) has a molecular weight of 56 kDa and is processed into sizes of 37 and 44 kDa. The p37 protein is included within p44 and antibodies raised against virions react against both proteins. The p44 protein is phosphorylated by host casein kinase II, whereas p37 is not phosphorylated. Both proteins contain a Zn-finger motif, which is implicated in RNA binding. It is not clear which of p37 and p44 is the mature capsid protein and if one or both are required for full infection.

Protease/Reverse Transcriptase (P5)

The CaMV P5 protein is a polypeptide which is cleaved into a 15 kDa aspartic protease on the N-terminus and a 60 kDa reverse transcriptase/RNase H. With the exception of *Petunia vein clearing virus*, the reverse transcriptases of the caulimoviruses do not have an integrase function and do not integrate into host chromosomes as part of their replication cycle. Nonetheless, caulimovirus nt sequences are frequently found in the genomes of plants due to illegitimate recombination events.

Transactivator/Viroplasm (P6)

The P6 protein of CaMV has a size of 62 kDa and is a target for plant defenses and it plays a key role in multiple steps of the viral replication cycle. P6 is the matrix protein for the formation of the electron dense inclusion bodies (IBs) (**Fig. 1(A)**), which are the site for translation of the polycistronic 35S RNA, reverse transcription of the 35S RNA into DNA, and encapsidation of the viral DNA into virions. Nearly all of the CaMV virions accumulate and are retained within the P6 IBs, and this has led to its designation as a “virion factory”. The role of P6 in translation is especially noteworthy, because the P6 protein interacts with and modifies host ribosomes to facilitate translation of the 35S RNA, essentially reprogramming eukaryotic ribosomes to deal with a polycistronic message. This function, designated the translational transactivator (TAV), is unique in nature. New functions have recently been discovered for the P6 protein, including (1) movement of P6 inclusion bodies on microfilaments for delivery of virions to modified plasmodesmata for transit to adjacent cells, (2) modification of host defenses associated with SA and JA pathways, and (3) functioning as a gene silencing suppressor. Furthermore, P6 is an important pathogenic determinant. In susceptible hosts, P6 has been shown to be a prominent symptom determinant, responsible for the chlorosis symptom in turnips and a systemic necrosis symptom in *Nicotiana clevelandii*. P6 has also been shown to be a target for host resistance proteins present in *Nicotiana* species and *Arabidopsis*; recognition of the P6 protein by a host resistance protein triggers a cascade of plant defense responses that results in limitation of spread of CaMV. To date, P6 has been shown to physically interact with 14 host or viral proteins to carry out such diverse roles as translational transactivation, intracellular movement and silencing suppression.

Replication and Propagation

Caulimoviruses replicate by reverse transcription of an RNA intermediate, but integration of the viral DNA into host chromosomes is not required to complete the replication process. **Fig. 3** illustrates the replication of an icosahedral caulimovirus, but the same steps

Fig. 3 Replication strategy of the members of the family *Caulimoviridae*.

are applicable for the bacilliform viruses. After virions enter a plant cell, the viral DNA becomes un-encapsidated and is transported into the nucleus. The viral DNA contains two to four single-stranded discontinuities, which form as a consequence of the reverse transcription process. Once in the nucleus, the single-stranded discontinuities are covalently closed and the DNA is associated with histones to form a minichromosome. The host RNA polymerase II is responsible for synthesizing an RNA that is terminally redundant; the sequence on the 5' end is reiterated on the 3' end. In the case of CaMV, the terminal redundancy is 180 nt in size, whereas the terminal redundancy in the CoYMV RNA is 120 nt. The terminally redundant RNA is transported out of the nucleus into the cytoplasm where it can either serve as a template for translation of viral proteins or as a template for reverse transcription. Reverse transcription is thought to occur in nucleocapsid-like particles.

First strand DNA synthesis is primed by a methionine (Met) tRNA that binds to a complementary sequence near the 5' end of the terminally redundant RNA. In the case of CaMV, the Met tRNA binds to a sequence approximately 600 nt from the 5' end of its 35S RNA. The virally encoded reverse transcriptase synthesizes DNA up to the 5' end of the terminally redundant RNA and the RNase H activity of the reverse transcriptase degrades the 5' end of the RNA. The terminal redundancies present in the genomic RNA provide a mechanism for a template switch, as the reverse transcriptase is able to switch from the 5' end of the genomic RNA to the same sequences on the 3' end of the genomic RNA and continue to synthesize the first strand of DNA.

The RNase H activity of the reverse transcriptase degrades the viral RNA template and small RNA fragments serve as the primers for second strand DNA synthesis. The RNA fragments bind to guanosine-rich tracts present in the first DNA strand, and these priming sites determine the positions of the discontinuities in the second DNA strand. A second template switch is required to bridge the gap from the 5' to the 3' end of the first DNA strand. The completion of the second DNA strand results in the formation of a dsDNA molecule that contains the characteristic single-stranded discontinuities.

Although caulimoviruses do not integrate into the host as part of their replication strategy, the sequences of several viruses have been detected in the genomes of their hosts. Furthermore, the integrated copies of several of these viruses, the Banana streak species, Tobacco vein clearing virus (TVCV) and PVCV, can be activated to yield episomal infections. All three viruses can form virions once episomal infections are initiated, but they differ in their capacity to be transmitted to other plants. Banana streak virus can be transmitted by mealybugs, whereas PVCV is transmitted only by grafting. TVCV and PVCV are transmitted vertically, through seed, but this probably involves only the integrated copies of the virus rather than the episomal forms.

The sites of integration are complex, as the viral sequences have undergone rearrangements, and multiple copies are arranged in tandem. Banana streak virus (BSV) is integrated at two loci in *Musa* chromosomes, TVCV is integrated at multiple loci in *Nicotiana edwardsonii* chromosomes, and PVCV is integrated into four loci in *Petunia hybrida* chromosomes. The mechanism that results in episomal infections remains to be elucidated, but there are some features common to all three viruses. First, the infections arise in interspecific hybrids. Consequently, each parent plant must contribute some factor to activate the integrated virus. Second, the infections arise after the hybrid has been exposed to some sort of stress. PVCV is activated when plants are exposed to water or nutrient stress, or the plants are wounded. TVCV infections arise in *N. edwardsonii* in the winter months in the greenhouse and are thought to be related to changes in light quality or duration. Integrated Banana streak virus sequences are activated in otherwise healthy *Musa* species when they are subjected to tissue culture. In each case, the virus is likely released through a series of recombination events or through reverse transcription of an RNA template.

Portions of other DNA viruses have been detected in plant chromosomes, but they have not been associated with episomal infections. This has led to speculation that plant DNA viruses might be capable of recombination in every infected plant, likely through a mechanism involving non-homologous recombination. However, since episomal forms of the caulimoviruses and badnaviruses have not been found in tissues fated for seed formation, the integrated forms would not appear in the next generation of plants. Consequently, the banana streak viruses, TVCV, and PVCV must have gained access to germline cells at some point such that their integrants would be passed through seed. This is likely to have been a relatively rare event.

Transmission, Host Range

Most members of the genus *Caulimovirus* are transmitted by as many as 27 species of aphids in a semi-persistent manner. The virions are acquired rapidly by the aphid and can be transmitted immediately upon acquisition. Virions can be maintained by the aphid for as little as 5 h up to three days, but are not retained after the aphid molts and are not passed on to aphid progeny. The protein products encoded by ORF-II (P2) and ORF-III (P3) are both required for aphid transmission. P3 forms a tetramer that binds to both the virion and to the C-terminus of P2. P2 is responsible for the binding of this complex to the aphid, as the N-terminus of P2 binds to a site in the aphid foregut. No insect vectors have been identified for species in the genera *Petuvirus*, *Rosadnavirus*, *Solendovirus*, *Soymovirus* or *Cavemovirus*.

None of the virions of the icosahedral viruses are transmitted through seed or pollen. Some viruses such as PVCV are transmitted from one generation to the next integrated into host chromosomes; at some point during the growth of the plant the integrated form of the virus is released from the chromosome and becomes capable of episomal replication. Most caulimoviruses are transmitted through mechanical inoculation, but there are a few exceptions, as PVCV, TVCV, Blueberry red ringspot virus, and Strawberry vein banding virus cannot be mechanically inoculated. In addition, most of these viruses are transmitted by grafting. In particular, Dahlia mosaic virus and Blueberry red ringspot virus infections in the field may be initiated through vegetative propagation or through grafting of infected plant material.

Badnaviruses are transmitted primarily by mealybugs, but a few are transmitted by aphids. Badnaviruses transmitted by mealybugs include the BSV species, the Sugarcane bacilliform viruses, Cacao swollen shoot virus (CSSV), Dioscorea bacilliform virus, Kalanchoe top spotting virus (KTSV), Piper yellow mottle virus (PYMoV), Taro bacilliform virus (TBV), and Schefflera ringspot virus. These viruses are transmitted in a semi-persistent manner and can be retained after molts, but do not multiply in the mealybug and are not transmitted to progeny. The badnaviruses shown to be transmitted by aphids include Gooseberry vein banding associated virus, Rubus yellow net virus (RYNV), Grapevine vein clearing virus, and Spiraea yellow leaf spot virus.

Other modes of transmission of the badnaviruses vary with the species. For example, CoYMV and KTSV can be mechanically inoculated, CSSV and PYMoV are mechanically inoculated with some difficulty, and RYNV and TBV have not been shown to be mechanically inoculated. The preferred method for inoculation of infectious badnavirus clones is agro-inoculation. Some of the badnaviruses are transmitted through seed, including the BSV, KTSV, and Mimosa bacilliform virus. KTSV is very efficiently transmitted by seed, with transmission rates from 60% to 90%, and is also transmitted in pollen.

RTBV is dependent on the RNA virus, RTSV, for its transmission. RTSV is vectored by a leafhopper, but causes only very mild symptoms. RTBV is only transmitted by the leafhopper in the presence of RTSV, but is responsible for the severe symptoms associated with the rice tungro disease. RTBV is not mechanically transmitted or carried in seed or pollen.

The host range of most caulimoviruses is fairly narrow, as in nature they generally infect plants within a single family (**Table 1**). Their experimental host range may extend to members of one or two other families, but in many instances, they may only infect a single genus of plants. There are a few exceptions. For example, the Sugarcane bacilliform viruses have a broader host range than most badnaviruses, as they can infect *Sorghum*, *Rottboellia*, *Panicum*, rice and banana. A limited host range can also be associated with similar limitations in the geographic distribution of the virus. For example, Soybean chlorotic mottle virus has only been recovered from a few samples in Japan. Perhaps the virus with the smallest geographic distribution is Stilbocarpa mosaic bacilliform virus, which has only been found on a single, small island in the subantarctic, midway between Tasmania and Antarctica. Other viruses, such as CaMV, Carnation etched ring virus and Dahlia mosaic virus are found worldwide, wherever their hosts are grown. Furthermore, the distribution of viruses that originate from integrated copies in their host's genomes, PVCV, TVCV, and the BSV species, are also closely aligned with the locations of their hosts. Interestingly, the icosahedral viruses of the caulimoviruses tend to infect hosts in temperate climates, whereas the bacilliform viruses of the badnavirus group are more likely to infect hosts in tropical or subtropical climates.

Virus-Host Relationships

Caulimoviruses induce a variety of systemic symptoms in their hosts, from chlorosis, streaking, and mosaics, to necrosis. The best-characterized pathogenicity determinant is the P6 protein of CaMV, as it has been shown to play a key role in the formation of chlorotic symptoms in turnips. This virulence function was first associated with P6 through gene-swapping experiments between CaMV isolates. It was confirmed when P6 was transformed into several species of plants, and in most cases, they exhibited virus-like symptoms. The P6 protein is also responsible for triggering systemic cell death in *Nicotiana clevelandii*, as well as a non-necrotic resistance response in *N. glutinosa*, and a hypersensitive resistance response in *N. edwardsonii*.

One feature that distinguishes the icosahedral viruses from the bacilliform viruses is that the former have the capacity to aggregate into amorphous inclusion bodies (Fig. 1(A)), whereas the latter do not form inclusions. The inclusion bodies formed by the icosahedral viruses are not bound by a membrane, can range in size from 5 to 20 μm , and occur in virtually all types of plant cells. The inclusions can be visualized with a light microscope in strips of epidermal tissue that has been stained with phloxine B. Close examination of CaMV inclusion bodies by electron microscopy reveals that there are actually two types. One type contains many vacuoles and consists of an electron-dense, granular matrix that is composed primarily of the P6 protein (Fig. 1(A)). A second, electron translucent type is made up of the P2 protein, a protein required for aphid transmission. Both types of inclusions are thought to have a role in the biology of the virus. The vacuolated inclusion bodies may be considered pathogen organelles, as they are thought to serve as the sites for replication of the viral nucleic acid, as well as translation of the 35S RNA and assembly of the virions. The electron translucent inclusions are considered to have a role in aphid transmission.

A second feature characteristic of the caulimoviruses is that the plasmodesmata of infected cells are enlarged enough to accommodate the virions, as electron micrographs have revealed the presence of CaMV and CoYMV virions in the enlarged plasmodesmata. For both CaMV and CoYMV, the alteration in size is mediated by their proteins required for cell-to-cell movement. In infected protoplasts, the CaMV P1 protein has been shown to induce the formation of tubular structures that extend away from the protoplast surface. It is hypothesized that virions are assembled in the cell and then are escorted to the enlarged plasmodesmata by the cell-to-cell movement proteins.

Glossary

Enzyme-linked immunosorbent assay A commonly used detection method of any protein that uses specific antibodies against the protein. All viruses have proteins on their particle surface, and are applicable for ELISA, if specific antibodies are prepared and mixed with an enzyme that accelerate colorization in the presence of the viruses.

Reverse transcription polymerase chain reaction A laboratory technique that consists of reverse transcription of

an RNA molecule into a DNA molecule and subsequent amplification of the DNA molecule using polymerase chain reaction (PCR). Specific amplification of the DNA molecule is ensured by using a set of specific short DNA molecules (designated “primers”) that are complementary to the target DNA.

Classification

The genera *Cheravirus*, *Sadwavirus*, and *Torradovirus* are taxa in the subfamily *Comovirinae* within the family *Secoviridae*. Each genus is distinguished from the other genera by its specific genomic organization, biological properties and phylogenetic relations. The member species of the genus *Cheravirus* are *Apple latent spherical virus* (ASLV), *Arracacha virus B* (AVB), *Cherry rasp leaf virus* (CRLV), *Currant latent virus* (CLV), and *Stocky prune virus* (StPV). The member species of the genus *Sadwavirus* is *Satsuma dwarf virus* (SDV). The member species of the genus *Torradovirus* are *Carrot torradovirus 1* (CaTV1), *Lettuce necrotic leaf curl virus* (LNLCV), *Motherwort yellow mottle virus* (MYMoV), *Squash chlorotic leafspot virus* (SCLSV), *Tomato marchitez virus* (ToMarV) and *Tomato torrado virus* (ToTV) (Table 1 and Fig. 1).

Virion Structure

Cheraviruses, sadwaviruses, and torradoviruses have the same virion structure as other viruses in the family *Secoviridae*. Virions are non-enveloped, and 25–30 nm in diameter. Cheraviruses and torradoviruses have three capsid proteins. Sadwaviruses have two capsid proteins. All cheraviruses, sadwavirus, and torradoviruses have two genomic RNAs that are encapsidated in separate virions. Many virus preparations also contain empty particles.

Genome Organization

The genome organization of cheraviruses, sadwaviruses, and torradoviruses consists of two single-stranded (+)-sense RNA molecules and their genomic organization is similar to that of the other viruses in the subfamily *Comovirinae*. The distinguishing features in the genome of cheraviruses are three capsid protein genes, and a comparatively small RNA2 that apparently encodes a single polyprotein. The unique features in the genome of sadwaviruses are the extensive amino acid sequence similarity in the N-terminal regions of the polyproteins encoded by RNA1 and RNA2. A unique feature of the torradovirus genome is the presence of a small open reading frame (ORF1) that is located upstream of, and partially overlaps with the large ORF2 in RNA2. The protein potentially encoded by RNA2-ORF1 shows no apparent homologies with other known proteins (Fig. 2).

^asubgenera organization of the *Sadwavirus* genus has yet to be ratified by the ICTV.

Fig. 1 Maximum-likelihood phylogenetic analysis of the cheraviruses, sadwaviruses, and torradoviruses using the amino acid sequence between protease domain and RNA polymerase domain in the RNA1 polyprotein. The percentage of trees in which the associated viruses clustered together in the bootstrap test (100 replicates) is shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. The amino acid sequence between protease domain and RNA polymerase domain in the RNA1 polyprotein of Enterovirus C (EVC) was used as an outgroup. For acronyms of the other viruses, see Table 1.

Fig. 2 Genomic organization of viruses in the genera *Cheravirus*, *Sadwavirus*, and *Torradovirus*. Schematic representation and the size of the genomes not reflecting their actual sizes. The figure is re-drawn from the figures published previously (Petrzik, *et al.*, 2016, Sanfacion *et al.*, 2009, van der Vlugt *et al.*, 2015) with modifications made by the authors. The same color box indicates the same domains in the polyprotein. For SMOV, the genomic organization of Canadian isolate SMOV-NsPer3 is shown here. The German isolate SMOV-1134 lacks the C-terminal protein domain of the RNA2 polyprotein. Abbreviations: CP, coat protein; CP-L and CP-S, large and small components of coat protein; MP, movement protein; NTB, nucleotide-binding protein (putative helicase); Pol, RNA dependent RNA polymerase; Pro, 3C-like protease; Pro-Co, protease cofactor; Pro-glu, glutamic protease; Vp-35, Vp-26 and Vp-24, viral protein (=coat protein) of about 35 kDa, 26 kDa, and 24 kDa; VPg, viral genome-linked protein. X1 domain was first reported in nepovirus and the function has not been characterized. X2 was also first reported for nepoviruses and it has sequence homologies with the Pro-Co of comoviruses. VPgs of viruses in the genera *Cheravirus*, *Sadwavirus*, and *Torradovirus* are putative.

Life Cycle and Epidemiology

Host Range

Natural hosts of cheraviruses include pome fruits, stone fruits, raspberry and currant as well as potato. The experimental host range of cheraviruses is broad or narrow, depending on the virus and strain. For example, CRLV, a cheravirus infects commercially cultivated cherry, apple, and potato, as well as wild herbaceous including dandelion, balsam root, and plantain. SDV, the type species of the genus *Sadwavirus* infects mainly citrus and occasionally *Daphniphyllum teijsmannii* and *Viburnum odoratissimum* var. *awabuki*. Torradoviruses were described to infect tomato or other crops like lettuce, carrot, squash and cassava, depending on virus species and strains. Little is known about other hosts but Tomato torrado virus (ToTV), the type species, infects over 20 weed species belonging to the family *Amaranthaceae*, *Chenopodiaceae*, *Solanaceae* etc., and the weeds apparently are ToTV sources for transmission to tomato (Figs. 3 and 4).

Geographic Distribution

Cheraviruses have been described from different countries worldwide; Apple latent spherical virus (Japan), Arracacha virus B (Peru), Cherry rasp leaf virus (the United States), Currant latent virus (the Czech Republic), and Stocky prune virus (France). Satsuma dwarf virus (*Sadwavirus*) occurs mostly in Japan but has been found also in China, Korea and Turkey. Tomato-infecting torradoviruses occur in some countries in Europa, in Australia, as well as some parts of North, Central and South America. LNLCV was found in the Netherlands and a CaTV1 torrado-like virus was found in the United Kingdom, France and Germany. MYMoV was detected only in Korea, while SLCV was detected only in Sudan.

Transmission

Among cheraviruses, CRLV is transmitted by a nematode (*Xiphinema americanum*) in the field and is seed-transmitted. Apple latent spherical virus, another cheravirus, is transmitted through seeds obtained from infected trees, and rarely through pollen. No vector

Fig. 3 Foliar symptoms of satsuma dwarf induced on satsuma mandarin. Satsuma mandarin showing small leaves with shortend internodes.

Fig. 4 Foliar symptoms induced on tomato with infection of ToTV. Necrotic spots surrounded by a light green or yellow area on young leaflets of ToTV-infected tomato. Photo courtesy by Martin Verbeek, Wageningen University and Research; copyright, Wageningen University and Research.

transmission was demonstrated for any sadwavirus, although field observation strongly indicated a soil-borne nature. Seed transmission of sadwavirus in citrus has not been tested, presumably because the main host of sadwavirus is a seedless satsuma mandarine, however it has been demonstrated in an experimental leguminous host. Tomato-infecting torradoviruses are the first spherical viruses reported to be transmitted by whiteflies (*Trialeurodes vaporariorum*, *Bemisia tabaci*, and *T. abutilonea*). No vector is known yet for carrot- and lettuce-infecting torradoviruses but these viruses are spreading in the open field, suggesting vector-involvement. Seed transmission of torradoviruses is very rare, if it occurs. Seed transmission of torradoviruses is still uncertain.

Clinical Features and Pathogenesis

Cheraviruses usually induce mild or no symptoms. Sadwavirus causes various foliar symptoms including smaller leaves, boat-shaped leaves with shortend internodes that lead to serious reduction in fruit quality and yield in citrus. Sadwavirus symptomlessly infects some wild trees including *D. teijsmannii* and *V. odoratissimum* var. *awabuki* near citrus fields. Some torradoviruses induce severe necrosis (in Spanish “torrado” meaning burned or roasted) on tomato leaves and fruits. The overall growth of the infected tomato plant is reduced and serious economic damage is inflicted. Torradoviruses infect other vegetables including carrot and lettuce, as well as herbs and wild plants.

Diagnosis

Cheraviruses, sadwaviruses, and torradoviruses are readily detected by RT-PCR. Generic RT-PCT that detect a wide range of viruses are available for cheravirus, sadwaviruses and tomato-infecting torradoviruses. Detection by ELISA using specific antibodies is possible for some cheraviruses, sadwaviruses and tomato-infecting torradovirus viruses.

Treatment

No treatment is available.

Prevention

Cheraviruses and sadwaviruses mainly infect fruit trees. In this case, movement of contaminated budwoods plays an important role in the long-distance dissemination. For example, occurrence of SDV in China, Korea and Turkey is obviously related to un-checked budwoods from Japan. Severe restriction on such practice is the first step of prevention. Some whitefly-transmitted torradoviruses affect tomato in greenhouses. In this case, damage would be alleviated by preventing whiteflies by suitable screens or sticky traps. Some level of genetic resistance appears to be available against ToTV. Possible sources of resistance for the other torradoviruses are not known.

Glossary

Cross-protection Prevention of the symptomatic phase of a disease by prior inoculation with a mild or non-symptomatic isolate of the same virus.

Defective RNA Subviral RNA molecules lacking parts of the genome while maintaining the signals enabling their synthesis by the viral replication system.

Genome The complete genetic information encoded in the RNA of the virus, including both translated and non-translated sequences.

Sub-genomic RNA Shorter than full length genomic RNA molecules produced during the replication process to allow translation of open reading frames.

Transgenic pathogen-derived resistance Plants genetically transformed to harbor viral or other pathogen derived sequences expected to confer resistance against related virus isolates.

Introduction

The virions of Citrus tristeza virus (CTV) are long flexuous particles ($2,000 \times 12$ nm) with an unusual architecture that results from two different coat proteins, the major coat protein (CP) and minor coat protein (CPm) encapsidation approximately 97% and 3%, respectively, of the helical structures. Two additional viral proteins, p61 and p64 (HSP 70 homolog) are required for efficient assembly. The 19.3 kb single stranded RNA genome is the longest among the plant viruses. Genomic analysis showed a division into twelve open reading frames (ORFs), the organization of which is conserved among all isolates. The ORF1a encodes a 349 kDa polyprotein containing two papain-like protease domains plus methyltransferase-like and helicase-like domains. Translation of the polyprotein is thought occasionally to continue through the polymerase-like domain (ORF1b) by a +1 frameshift. Ten 3' ORFs are expressed by 3' co-terminal sub-genomic messenger RNAs. Infected cells contain a myriad of other sub-genomic RNAs. In addition, most CTV isolates contain one or more defective RNAs of different sizes and genomic rearrangements. Among the CTV translation products, at least 3 function as RNA silencing repressors, which are serving to protect the extremely large size CTV genome and correlated with unusual difficulty in conferring effective pathogen derived resistance to transgenic citrus plants.

This article is essentially reporting all the basic elements of the knowledge about CTV including CTV population genomic studies, as well as the use of bioinformatic tools, and the development of the CTV gene cloning vector, that allows elucidating the functional genomics of both CTV and its citrus hosts.

Although CTV is still considered to be among the most important plant viruses, the attention of the world's citrus growers to the significance of CTV research has apparently diminished. We may attribute this decline in interest, at least in part, to the efficacy of control measures introduced in modern citriculture which are based on (1) CTV-tolerant or resistant rootstocks; and (2) effective selection of mild CTV strains that are providing commercially acceptable cross-protection against severe stem-pitting CTV isolates. However, despite

the general decline in CTV research, the major reason that supports recent CTV research is related to the catastrophic damage experienced during the last 15 years by citrus growers in Brazil and Florida as a result of infection with “*Candidatus Liberibacter asiaticus*” bacteria. Finding effective means for controlling this bacterium, the causal agent of huanglongbing/greening (HLB) disease, is currently the focus of intense research efforts. Nevertheless, CTV-related problems have not been completely eliminated, and the danger of spread of severe CTV isolates, once the brown citrus aphid reaches the Mediterranean and Californian citrus, remains a continuous threat.

History

Over the last 90 years *Citrus tristeza virus* (CTV) has killed or rendered unproductive millions of trees throughout most of the world's citrus growing areas and hence it is rightfully considered as the most important virus of the world's largest fruit crop, citrus, hence the name “tristeza” which means “sadness” in Spanish and Portuguese. However, as with many other disease agents, the actual damage of CTV infections and the timings varied considerably at different periods and geographical regions. The origins of CTV infections remain unknown; the virus however existed for centuries in Asia as an unidentified disease agent, but growers in these areas adapted citrus varieties and rootstock combinations with resistance or tolerance to CTV infections. Out of Asia, citrus production moved to the Mediterranean region, primarily through the introduction of fruit and propagation of seed which does not transmit CTV to the resulting plantings; hence, the new cultivation areas started from seed sources remained free of the virus for centuries. However, the improvement in maritime transportation, allowing long distance transport of rooted citrus plants – led to the outbreak of the deadly citrus root rot disease caused by *Phytophthora sp.*, which was managed by adapting the more tolerant sour orange rootstock. The considerable horticultural advantages offered by this rootstock coincided with the large-scale expansion of plantings throughout the Mediterranean and American countries, and as a result citrus production in many areas was almost entirely based on that single rootstock. This decision had grave subsequent effects when CTV pandemics swept throughout the world, causing “quick decline” (death) of trees on this rootstock. Although the CTV problems were first noticed in South Africa and Australia where, by the end of the 19th century, the growers have found that sour orange was an unsuitable rootstock, it was only in the 1930s that the extent of this deadly disease problem manifested itself first in Argentina and shortly later in Brazil and California, with the death of millions of trees.

The virus-like nature of the tristeza-related diseases was demonstrated experimentally by graft and aphid transmission of the disease agent in 1946; however, description of CTV properties began with the seminal findings of thread-like particles associated with tristeza-infected trees. These unusually long and thin particles presented a challenging problem for isolation (purification), which was an essential step towards virus characterization. Development of effective purification methods and biophysical characterization of CTV and similar viruses led to their assignment to the *Closterovirus* group of elongated viruses. The association of infectivity with the thin-particle-enriched preparations was demonstrated early on; however, the unequivocal completion of Koch's postulates was only completed in 2001 with the mechanical infection of citrus plants with RNA transcripts of an infectious CTV cDNA clone amplified through serial passaging in *Nicotiana benthamiana* protoplasts.

Development of CTV purification methods paved the way to antibody preparations and to improved CTV diagnosis by ELISA which demonstrated considerable serological diversity among CTV isolates. Later, RNA extracts from CTV-enriched particle preparations were used for molecular cloning of cDNA molecules, which when used as probes confirmed considerable genomic variation among CTV isolates. Nucleic acid probes also demonstrated that plants infected with CTV and other closteroviruses contained many defective RNAs (dRNAs) in addition to the normal genomic and sub-genomic RNAs. Infected plants also contain unusually large amounts of dsRNAs corresponding to the genomic and sub-genomic RNAs. Because of the ease of purifying these abundant dsRNAs, they often have been the template of choice for producing cDNAs. The advent of cDNA cloning of CTV led to the sequencing of its genome and to description of the defected (d)RNAs.

Taxonomy and Classification

CTV belongs to genus *Closterovirus*, family *Closteroviridae*. The *Closteroviridae* family contains more than 30 plant viruses with flexuous, filamentous virions and with either mono- or bipartite single-stranded (one tripartite) positive sense RNA genomes. A recent revision of taxonomy of the *Closteroviridae* based on vector transmission and on phylogenetic relationships using three proteins highly conserved among members of this family (a helicase, an RNA dependent RNA polymerase, and a homolog of the HSP70 heat-shock proteins) led to defining of three genera: *Closterovirus* including CTV and other aphid-borne viruses with monopartite genomes, *Ampelovirus* comprising viruses with monopartite genomes transmitted by mealybugs, and *Crinivirus* that includes whitefly-borne viruses with bipartite or tripartite genomes. Closteroviruses are all phloem-limited viruses. Among the hallmarks of the group is the presence of a conserved five-gene-module that includes the four proteins involved in assembly of virions, the major (CP) and minor (CPm) coat proteins, p61, and p64, a homolog of the HSP70 chaperon. In addition, infected phloem-associated cells have clusters of vesicles considered specific to closterovirus cytopathology (Fig. 1).

Fig. 1 An electron micrograph of a thin section from a Mexican lime (*Citrus aurantifolia*) young leaf vein showing typical symptoms of vein clearing following infection with the Floridian T36 isolate of Citrus tristeza virus. Note the clusters of vesicles typical of infections by closteroviruses. The bar represents 250 nm.

Geographic Distribution

Citrus is a common fruit crop in areas with sufficient rainfall or irrigation from the equator to about 41 degrees of latitude north and south. CTV is now endemic in most of the citrus growing areas, with only a few places in the Mediterranean basin and Western USA remaining free of CTV infections. The recent spread of the brown citrus aphid (*Toxoptera citricida*) to parts of Portugal and Spain are threatening most of the remaining CTV-free areas of the Mediterranean basin. One important aspect of CTV geographic distributions is that some area that have endemic isolates of CTV still do not have the most damaging stem-pitting isolates. With the spread of the vector comes the threat of extremely severe CTV isolates which so far have not spread to North America and Mediterranean countries.

Economic Costs of CTV

Control strategies varied at different geographic regions and periods, depending on the extent to which CTV was spreading within the newly infested areas, the sensitivity of the specific local varieties, and the economical availability of alternative crops to replace diseased groves. Most citrus growing countries that managed to remain free of CTV did so by enforcing sanitation practices to prevent virus spread. These included certification schemes aimed to ensure that citrus nurseries propagate and distribute to growers only CTV-free planting material. Other areas had far more costly and ambitious programs of eradication. These efforts were mostly only temporarily successful, mainly because of lack of long-term grower and governmental commitment to such costly operation. In areas where CTV was endemic, alternative strategies to enable continued commercial citrus production in the presence of CTV were developed. Indeed, long before the viral nature of the tristeza disease was realized, Japanese citrus growers were grafting CTV-tolerant Satsuma mandarins on the cold-tolerant and CTV-resistant trifoliate orange (*Poncirus trifoliata*) rootstock, thus enabling them to produce quality fruits despite endemic CTV infections. Similarly, change of rootstocks from the “quick declining” sour orange rootstocks to rough lemon rootstocks, and to less extent mandarin rootstocks, allowed the South African growers to produce good crops of oranges despite the presence of the most efficient aphid vector and infections with severe CTV strains. Similarly, half a century later the Brazilian citrus industry that was completely decimated during the 1940s, when all trees were grafted on sour orange rootstocks, was saved by adopting CTV-tolerant rootstocks and mild strain cross-protection.

Historically the costs of CTV epidemics were estimated to be of the order of tens and even hundreds of millions of dollars. These estimates, however, varied depending on actual market value of the lost production capacity, alternative uses of the land, and the time needed for the CTV-tolerant replants to enter production. There were also indirect costs resulting in poorer performance and/or sensitivity of some CTV-tolerant rootstocks used to replace the widely adapted sour orange rootstocks to other citrus diseases such as citrus blight and citrus sudden death.

Host Range and Cytopathology

CTV infects all species, cultivars and hybrids of *Citrus sp.*, some citrus relatives such as *Aeglopsis chevalieri*, *Afraegle paniculata*, *Fortunella sp.*, *Pamburus missionis* and some intergeneric hybrids. Species of *Passiflora* are the only non-Rutaceous hosts, infected naturally. The CTV decline isolates in trees on sour orange rootstocks (Fig. 2) are associated with the death of the phloem near the

Fig. 2 Symptoms of CTV on different citrus species: (A). decline of sweet orange on sour orange rootstock, (B & C) seedling yellows on Duncan grapefruit.

bud union, resulting in a girdling effect that may cause the overgrowth of the scion at the bud union, loss of feeder roots and thus drought sensitivity, stunting, yellowing of leaves, reduced fruit size, poor growth, dieback, wilting, and death. However, other virulent and damaging CTV strains cause stem pitting (SP), which results in pits in the wood under depressed areas of bark and are often associated with severe stunting and considerably reduced fruit production. The seedling-yellow reaction (SY) which includes severe stunting and yellowing on seedlings of sour orange, lemon and grapefruit is primarily a disease of experimentally inoculated plants but might also be encountered in the field.

CTV infection is closely restricted to the phloem tissues of infected plants that first show chromatic cells filled with either aggregates of virus particles and/or necrotized cytoplasm. Interestingly, the death of trees on the sensitive sour orange rootstock is not associated with increased amounts of chromatic cells, thus suggesting a different patho-physiological condition lead to the chromatic type of cell death, which could also be observed in tissues of sweet orange trees which are tolerant to CTV when growing on their own roots.

Nicotiana benthamiana has become an important experimental host for CTV since it was discovered that plants become systemically infected by *Agrobacterium tumefaciens* containing recombinant DNA plasmids of CTV (agro-inoculation).

The CTV Virions

The CTV virions are long flexuous particles, 2000 nm long $\times$ 10–12 nm in width (**Fig. 3**). The virions have helical symmetry with a pitch of 3–4 nm, about 8–9 capsids per helix turn, and a central hole of 3–4 nm. Unlike the virions of other elongated plant viruses that consist of cylindrical nucleocapsids made of a single CP, the CTV virions consist of bipolar helices with a long body and short tail. Immuno-electron microscopy showed antibodies to CPm attached to only one end of the virions, with the major part (>97%) of the virion is encapsidated by CP. Interestingly, the “tail” corresponds to the 5' end region of the viral genome and the tails of other closteroviruses have been associated with small amounts of p61 and HLP60h.

The CTV Genome

Fig. 4 shows a schematic presentation of the 19.3 kb CTV RNA. Generally, the CTV genome is divided almost equally into two parts, the 5' part consisting of ORF1a and 1b harboring the viral replication machinery and the 3' end half harboring 10 ORFs

Fig. 3 Particles of CTV, with a diameter of 10–12 nm, negatively stained with Uranyl acetate. Note their flexible thread like shape, considerably limiting the possibility of their isolation from infected citrus tissues. The bar represents 50 nm.

Fig. 4 A schematic presentation of the citrus tristeza virus (CTV) genomic (g) and subgenomic (sg) RNAs. The replication-associated ORFs are highlighted in blue, the five-gene structural and assembly block common to all closteroviruses in yellow, suppressors of silencing in red, and three genes on undetermined function in green. Lines shown on the left and right side below the genomic map indicate 5' large molecular single stranded (ss) 5' sgRNA (LaMT) and two low molecular ssRNAs (LMT1 and LMT2) and a nested set of 3' co-terminal sgRNAs, respectively. The left insert shows Northern blot hybridization of dsRNA enriched extracts from an Alemow plant infected with the VT strain of Citrus tristeza virus (CTV-VT) using Riboprobes specific to the 5' end of the viral RNA. Note the presence of the large replicative form (RF) molecules (upper band), LaMT and two abundant LMT molecules. The right insert shows hybridization of dsRNA with a 3' UTR probe. Note the hybridization bands of the different 3' sgRNAs indicated by arrows.

encoding a range of structural components and other gene products involved in virion assembly and host and vector interactions. CTV replicons containing only ORFs 1a and 1b plus the 5' and 3' non-translated ends (**Fig. 4**) fulfill all the requirements for efficient replication in protoplasts.

Interestingly, while the sequences of the 3' half of all CTV isolates that have been sequenced are 97% and 89% identical, the 5' half sequences often differ considerably more. For instance, the isolates T36 and VT show only 60%–70% identities for their 5' halves.

The Untranslated Regions (UTRs)

A remarkable feature of CTV isolates are the close identities (97%) of their 3' NTR primary sequences compared to the considerable divergence of their 5' UTR sequences. Computer assisted calculations, however, suggest that not only the 3' UTRs of different isolates fold into similar predicted structures, but surprisingly the dissimilar sequences of the 5' NTRs also are predicted to fold into similar secondary structures. The 3' replication signal of several CTV isolates was mapped to 230 nt within the UTR and predicted to fold into a secondary structure composed of 10 stem-and-loop (SL) structures. Three of these SL regions and a terminal 3' triplet, CCA, are essential for replication. Replacement of T36 3' UTR with 3' UTRs from other strains allowed

replication, albeit with slightly less efficiency, suggesting on the significance of the primary sequence of this part. The plus-strand sequence of the 5' UTRs from different strains are predicted to form similar secondary structures consisting of two stem-loops (SL1 and SL2) separated by a short spacer region, that were essential for replication and initiation of assembly by CPm.

Gene Functions

In infected cells, the 12 ORFs of CTV (**Fig. 4**) are expressed through a variety of mechanisms including: proteolytic processing of the polyprotein, translational frame shifting, and production of 10 3' co-terminal sub-genomic RNAs. The first two mechanisms are used to express proteins encoded by the 5' half of the genome while the third mechanism is used to express ORFs 2–11. The ORF1a encodes a 349 kDa polyprotein containing two papain-like protease domains plus methyltransferase-like and helicase-like domains. Translation of the polyprotein could also continue through the polymerase-like domain (ORF1b) by a +1 frameshift. These proteins along with the signals at the 5' and 3' ends of the genome are the minimal requirements for replication of the RNA. The function of p33 (ORF2) is required for superinfection exclusion and is required for infection of a subset of the viral host range. The next five gene products from the 3' genes include the unique signature block characteristic of closteroviruses, which consist of the small, 6 kDa hydrophobic protein (ORF3), 65 kDa cellular heat-shock protein homolog (HSP70h, ORF4), 61 kDa protein (ORF5), and the tandem pair of p27 (CPm, ORF6) followed by p25 (CP, ORF7). The four proteins with the exception of p6 are required for efficient virion assembly. The small hydrophobic p6 is a single-span trans-membrane protein not required for virus replication or assembly, but it is required for infection of all plants of the host range. CP is also a suppressor of RNA silencing. The function of p18 (ORF8) and p13 (ORF9) are required for infection of certain hosts. Protein p20 (ORF10) accumulates in amorphous inclusion bodies of CTV-infected cells and has been shown to be a suppressor of RNA silencing. p23 (ORF11) is a multifunctional protein with no homolog in other closteroviruses, that: (1) binds cooperatively both single-stranded and dsRNA molecules in a non-sequence-specific manner (2) contains a zinc finger domain that regulates the synthesis of the plus- and minus-strand molecules and controls the accumulation of plus-strand RNA during replication (3) is an inducer of CTV-like symptoms in transgenic *C. aurantifolia* plants and (4) is a potent suppressor of intracellular RNA silencing in *Nicotiana tabacum* and *N. benthamiana* and (5) controls the level of negative-stranded of genomic and sub-genomic RNAs. For additional p33 functions, see also Virus-Virus, interactions.

The CTV Sub-Genomic RNAs

The replication of CTV involves the production of large number of less than full-length RNAs. These include ten 3' co-terminal sg mRNAs, and ten negative-stranded sgRNAs corresponding to the ten 3' sg mRNAs, plus ten 5' co-terminal sgRNAs that apparently are produced by termination just 5' of each of the 10 ORFs (**Fig. 4**). The amounts of different sg mRNAs vary with the highest levels for sg mRNAs p23 and p20, located at the distal 3' end. Infected cells also contain abundant amounts of two other small 5' co-terminal positive-stranded sgRNAs of ~600 and 800 nt designated as low molecular weight tristeza (LMT).

Defective RNAs

Most CTV contain defective RNAs (dRNAs), which consist of the two genomic termini, with extensive internal deletions, resulting in different sizes of 5' and 3' sequences. CTV dRNAs accumulate abundantly in infections with wild type virus. The dRNAs contain different sizes of 5' and 3' sequences. The biological roles of CTV dRNAs remain obscure as no clear cut associations have been established with any of the dRNA.

Virus-Virus Interactions

The CTV isolates were categorized as strains based on biological properties. Major genetic differences between CTV isolates were reported using a CTV specific cDNA probe of the VT strain. Cross-protection is a practice in which a mild population of CTV is purposely pre-inoculated into trees to prevent infection and disease caused by endemic isolates. Cross-protection has been widely used to allow commercial citrus production in regions with severe endemic isolates of CTV. It works well when an effective protecting isolate is found, but this process is empirical and difficult. Most mild isolates fail to protect and finding the correct combination has consumed whole careers. The successful protecting isolate must affect a virus-virus interaction such that the protecting isolate interferes with establishment of infection and induction of disease symptoms. A component of this process is superinfection exclusion. It has been shown that previously established infections of CTV can completely exclude superinfection by another isolate. However, this is limited to isolates from the same strain of CTV. Challenges with isolates of different strains of CTV are not inhibited. This superinfection exclusion is dependent on the p33 gene and/or the 5' protease. For example, as the full-length virus can completely exclude an isolate from the same strain, CTV with the p33 gene deleted does not. Thus, one component of finding or creating a protecting virus against a pathogenic endemic isolate is to identify the sequence group (strain) of the cause of disease, challenging isolates and choose or create a mild isolate from the same strain.

Fig. 5 A diagram of class 1 CTV defective (d) RNAs with three different sizes and class 2 CTV-dRNAs that show 3' moieties of the size and structure of the full-length sgRNA of ORF11. Inserts A and B show Northern hybridization of class 1-dsRNAs from three different CTV-VT sub isolates, hybridized with Riboprobes specific for the 5' and 3' ends of the CTV gRNA, respectively. Note the intense bands resulting of the hybridization with both probes of the abundantly present dRNAs. Lower part is a diagrammatic presentation of direct repeats at the junction sites of some class 1 dRNAs. The bottom part shows a schematic presentation of a class 2 dRNA, with a 3' terminus corresponding to the ORF11 sgRNA of CTV-VT.

However, since most endemic isolates are populations made up of components from several strains, in practice it is not that simple because so far effective protecting isolates also are population. Thus, this requires an understanding of the rules of populations. For example, a typical population might consist of 50% strain A, 20% strain B, 29% strain C, and 1% strain D.

CTV has at least seven characterized genotypes, defined by nucleotide sequence divergence of ~10%–20% from each other. **Fig. 5** shows a Phylogenetic tree of 60 CTV isolates belonging to different CTV strains (circles). These CTV genotypes differ in their infectivity in different citrus species, tropism and ability to move systemically, vector transmissibility and to some extent, pathogenicity. It should be noted, however, that there is variability in biological properties even between isolates or variants of the same genotype (**Fig. 6**).

As a virus with multiple, distinct genotypes, and a long-lived host system, it is unsurprising CTV isolates from field trees almost always consist of populations of multiple genotypes in mixture. The existence of multiple genotypes within an individual plant, and co-infection of the same cells also explains the frequency of recombination observed for CTV isolates. The CTV genotypes within individual plants both compete and interact with one another, reaching equilibrium based on their relative fitness vis-à-vis one another, and the host. A major rule of equilibrium of mixtures of genotypes in a population is determined by the host, which could explain why cross-protection often breaks down upon utilization of new citrus varieties. Also, individual CTV genotypes or variants are also capable of interacting via complementation to increase fitness and overcome tropism limitations as well as increasing the efficacy of aphid transmission.

Transmission

Although the virus is phloem-limited, mechanical inoculation can be done experimentally at relatively low efficiency by slashing the trunks of small citrus trees with blades containing sap extracts. In commercial groves, the virus is spread naturally by aphid vectors and by vegetative propagation in infected budwood. Long distance spread of the virus, particularly from country to country, had been through the long-distance transfer of plant propagation materials.

Several aphid species including *Aphis gossypii*, *A. spiraeicola*, *A. craccivora*, and *T. citricida* transmit CTV semi-persistently. The rate of transmissibility varies considerably between different virus isolates and different aphid species. Transmission efficacy of *T. citricida* is approximately 6 to 25 times more efficient than *A. gossypii*, and different CTV isolates or genotypes can differ dramatically, for example 40%–60% for the type isolate of strain T68 to less than 1% for type isolate or strain T36. However, it

Fig. 6 (A) Phylogenetic tree and evolutionary analysis of 60 full-length citrus tristeza virus (CTV) genome sequences using the maximum-parsimony method. The CTV isolates belonging to different CTV strains are indicated by circles, with permission from the author Yokomi, R.K., Selvaraj, V., Maheshwari, Y., *et al.*, 2017. Identification and characterization of citrus tristeza virus isolates breaking resistance in trifoliate orange in California. *Phytopathology* 107, 901–908. (B) A phylogeny of displaying the major Citrus tristeza virus (CTV) genotypic groupings, generated using the maximum-parsimony method from complete genomic sequences.

should be noted that other isolates of the T36 strain are much more highly transmitted and the type isolate was originally isolated from a tree infected by aphid transmission. Apparently, more than 50 years of graft transmission of the type isolate of T36 resulted in loss of aphid transmission. Transmission efficacy can also be affected by the interaction of CTV genotypes in mixture, where the presence of highly transmissible variants can increase the transmission rate of poorly transmissible variants through complementation.

For the semi-persistent mode of transmission, the virion has been found to bind to the cibarium and foregut of the aphid vector via interaction of the p27, p61 and p65 proteins. Additionally, the p33 protein has also found to be involved in enhanced transmission.

CTV Control Measures

Strategies to control CTV have varied at different locations and periods and included (1) quarantine and budwood certification programs to prevent the introduction of CTV, (2) costly and ambitious eradication programs to contain situations of virus spread, (3) the use of CTV-tolerant rootstocks and mild (or protective) strain cross-protection, often also named preimmunization, (4) breeding for resistance, and (5) attempts to obtain resistance by genetic engineering. Mild strain cross-protection has been widely applied for millions of citrus trees in Australia, Brazil, and South Africa to protect against stem pitting of sweet orange and grapefruit trees. However, mild strain cross-protection has not provided field protection against CTV isolates causing quick decline of trees on the sensitive sour orange rootstock.

Useful resistance to CTV has been found in a citrus relative, *Poncirus trifoliata*. This resistance has been mapped and shown to be controlled primarily by a single genome region and sequenced. However, a specific gene has not been identified by transformation into susceptible citrus resulting in a resistance phenotype.

CTV Diagnosis

The outcome of CTV infections varies considerably depending the virulence of the prevailing virus isolates, and sensitivity of infected citrus varieties and rootstock combinations. Hence, the need for diagnosis is of utmost importance. Biological indexing of the disease by grafting sensitive citrus indicators has been the definitive assay, although it is costly and time consuming. It has largely been replaced with more rapid immunoassays (ELISA) that have been widely practiced for almost 30 years for a variety of CTV sanitation programs. Development of recombinant antigens considerably advanced diagnostic possibilities and production of monoclonal antibodies has allowed for more precise differentiation of isolates. PCR and combinations of immuno-capture PCR allow more sensitive CTV diagnosis. Recently, high-

throughput sequencing has proven an effective tool for the rapid identification of CTV isolates and populations. However, despite the development of better detection tools, none are effective for predicting the biological properties of new CTV isolates.

Attempts to Apply Transgenic Resistance to CTV

Conventional breeding for CTV resistance is a long, difficult, and inconvenient process mainly because most citrus varieties are hybrids of unknown parentage. Hence the considerable interest in applying pathogen derived resistance (PDR) to render both citrus rootstocks and varieties resistant to stem pitting isolates and decline causing CTV isolates. Yet, literally hundreds of independent transformations with a range of different configurations of CTV sequences has resulted in failure to obtain durable protection against CTV. These failures are especially frustrating since the control of severe stem pitting isolates is needed in several major citrus producing. Several reports on transgenic resistance to CTV infection including effective protection of plants expressing the three CTV silencing suppressor genes need still validation under field conditions. The lack of RNA silencing against CTV in citrus might be due to more effective suppression by the combination of the three suppressors of this virus.

Epilogue

As indicated in the preface, in much of the world's citrus-growing regions, CTV is now considered a manageable disease. Nevertheless, research is still needed to address several important questions such as the spread of severe CTV isolates and the brown citrus aphid into regions previously free of them, and a re-emergence of CTV as serious economic plant pathogen of citrus. We still do not know the origin of CTV; did it originate from one of the many wild relatives of domesticated citrus, or from another plant family and subsequently adapted to citrus?

CTV and its host interactions especially in Pummello, one of the three ancestors of citrus also remains to be elucidated, especially as both the highly CTV sensitive sour orange and the tolerant sweet oranges share both Pummello and mandarins as parents. Similarly questions of CTV genome variation are worth attention noting the considerable variation between the 5'-terminal regions of the genomes of T36 and VT strains raises the possibility of a long-time separation from the original source, does the parental strain still survive and, if so, could the related genome re-emerge as a new pathogen based on its genome and biology?

Finally, it is interesting to note that recent molecular studies of phloem-limited bacteria, such as the greening agent, indicated a drastic reduction in their genome size, compared to the majority of non-phloem-limited bacteria; whereas, CTV, with the largest genome of the family *Closteroviridae*, behaves just the opposite. The question thus remains why and how CTV adopted such a different survival strategy within the phloem vessels of its host plants.

Closteroviruses (*Closteroviridae*)

Marc Fuchs, Cornell University, Geneva, NY, United States

© 2021 Elsevier Ltd. All rights reserved.

Nomenclature

aa amino acid(s)
AlkB alpha-ketoglutarate-dependent hydroxylase domain
CP coat protein or capsid protein
CPm minor coat protein
ELISA enzyme-linked immunological assays
ER endoplasmic reticulum
HC-Pro helper component-protease
HEL helicase
HSP70h heat shock protein 70 homolog

kb kilobase
kDa kilo dalton
LAMP loop mediated amplification
L-Pro leader papain-like protease
MET methyltransferase
MP movement protein
nt nucleotide(s)
ORF open reading frame
RdRp RNA-dependent RNA polymerase
UTR un-translated region

Glossary

Ampelovirus One of the four genera in the family *Closteroviridae*. The name ampelo derives from the Greek *ampelos*, "grapevine", the natural host of grapevine leafroll-associated virus 3, the type species of the genus *Ampelovirus*.
Closterovirus Another genus in the family *Closteroviridae*. The name *clostero* derives from the Greek *kloster*, "spindle, thread" due to the size and appearance of very long, flexuous, and helically constructed filamentous virions.
Crinivirus It is another genus in the family *Closteroviridae*. The name *crini* derives from the Latin *crinis*, "hair", for the appearance of the very long thread-like particles.

RNA-dependent RNA polymerase An enzyme that catalyses the transcription of RNA from an RNA template.
tRNA-like structure An RNA sequence with a similar tertiary structure to transfer RNA.
Velarivirus It is the most recently identified genus in the family *Closteroviridae*. The name *velari* derives from the Latin *velari*, "cryptic or veiled", because *Grapevine leafroll-associated virus 7*, the type species of this genus, does not cause any apparent disease symptoms on its natural host.

Introduction

Plant viruses of the family *Closteroviridae* belong to the higher phylum *Kritrinoviricota* in the realm *Riboviria*. Their common features include the morphology and size of virions, the genome structure and expression, the presence of canonical conserved proteins, characteristic cytopathic structures, tissue tropism, transmission by specific hemipteran insects in a semi-persistent manner, and extreme difficulties at mechanical transmission to herbaceous hosts (Table 1).

Virions have a diameter of about 12 nm and lengths ranging from 650 nm for species with a fragmented genome to over 2000 nm for species with a monopartite genome (Table 2). Virions are helically constructed filaments with a pitch of the primary helix in the range of 3.4–3.8 nm, containing about 10 protein subunits per turn of the helix and showing a central hole of 3–4 nm (Fig. 1). Two types of coat protein (CP), the major CP and a CP analog or minor CP (CPm), are the most abundant protein components involved in the formation of most virions with CPm encapsidating the 600–700 nt 5'-terminal of the viral RNA and coating one extremity (75–100 nm) of the particles, thus forming a distinct structure referred to as rattlesnake or bipolar. The virus-encoded heat shock protein 70 homolog (HSP70h) of cell chaperones and the ~60 kDa proteins are also integral virion components. The ~60 kDa protein is required for incorporation of both HSP70h and CPm to virions, which also incorporate a 20 kDa protein that may form the tip segment of the virion head.

Species demarcation criteria used for all genera in the family *Closteroviridae* are particle size, size of the CP, genome structure and organization, vector species and specificity, cytopathological features, host range, as well as aa sequence of the RNA-dependent RNA polymerase (RdRp), CP, and HSP70h differing by more than 25%.

Classification

Plant viruses in the family *Closteroviridae* are divided into four genera: *Closterovirus* (monopartite genome), *Ampelovirus* (monopartite genome), *Velarivirus* (monopartite genome) and *Crinivirus* (bipartite or tripartite genome) (Table 2). Collectively these viruses are referred to as closteroviruses, the generic name for viruses in the family that was initially coined for this group of plant viruses by

Table 1 Common features among members of the family *Closteroviridae*

<i>Virions</i>	<i>Genome structure</i>	<i>Genome organization</i>	<i>Genome expression</i>	<i>Cytopathic structures</i>	<i>Tissue tropism</i>	<i>Transmission</i>	<i>Mechanical inoculation</i>
Long, helically constructed filamentous particles (650–2200 nm in length and 12 nm in diameter)	A very large positive sense, single-stranded RNA (12,000 to nearly 19,000 nt) with an organization distinct from those of other plant viruses	Two conserved gene modules encoding proteins associated with replication with a close phylogenetic relationship (ORF1a and 1b) and a quintuple gene module encoding proteins associated with replication, virion formation, cell-to-cell movement and suppression of RNA silencing; and a unique set of genes coding a heat shock protein 70 homolog, and for a duplicated, diverged copy of the coat protein (minor coat protein, CPm)	Proteolytic processing, +1 ribosomal frameshift, and the production of sub-genomic RNAs	Cytoplasmic aggregates of virions intermingled with single or clustered membranous vesicles	Phloem restriction with occasional location in the mesophyll and epidermis	Aphids, whiteflies, mealybugs and soft scale insects	Extremely difficult for a extremely limited number of virus species

Table 2 Distinguishing properties of the four genera in the family *Closteroviridae*

Genus	Virion length (nm)	RNA species (#)	Genome size (kb)	ORF (No.)	Replicase (kDa)	HSP70h (kDa)	CP (kDa)	CPm (kDa)	Vector
<i>Closterovirus</i>	1350–2000	1	14.5–19.3	8–12	349–367	65–67	22–25	24–27	Aphids
<i>Ampelovirus</i>	1400–2200	1	13.0–18.5	7–12	245–293	57–59	28–36	50–56	Mealybugs, soft scales
<i>Crinivirus</i>	650–850 and 700–900	2 or 3	7.8–9.1/7.9–8.5 8.0–5.3–3.9	9–13	267–280	62–65	28–29	53–80	Whiteflies

Fig. 1 Electron micrographs of virions of Beet yellows virus (BYV) from the genus *Closterovirus* that are negatively stained and decorated with an antiserum specific to the (a) coat protein (CP) -note that the CP minor (CPm) tail is not decorated-, and (b) CPm at the 75 nm tail of a virus particle. (c) Close-up of the 75 nm tail of four selected BYV particles decorated with an antiserum specific to CPm. Scale bars represent 300 nm. From Agranowsky, A.A., Lesemann, D.E., 2000. Beet yellows virus. Descriptions of Plant Viruses. Association of Applied Biologists. Available at: <http://www.dpvweb.net/dpv/showdpv.php?dpvno=377>, with permission.

the International Committee on Taxonomy of Viruses in 1976. In addition to classified viruses in the family, a few species are unassigned members in the family *Closteroviridae*: *Actinidia virus 1*, *Alligatorweed stunting virus*, *Blueberry virus A*, *Megakepasma mosaic virus*, *Mint vein banding-associated virus*, *Olive leaf yellowing-associated virus*, and *Persimmon virus B*.

The genus *Closterovirus* comprises 14 species with particles ranging from 1350 to 2000 nm in length, and a monopartite, positive-sense, single-stranded RNA genome, 14.5–19.3 kb in size, in which the CPm is uniquely located upstream of the CP. The natural transmission of closteroviruses is by aphids (**Table 2**). *Beet yellows virus* (BYV) is the type species of the genus *Closterovirus*.

The genus *Ampelovirus* comprises 13 species with particles ranging from 1400 to 2000 nm in length, and a monopartite positive-sense, single-stranded RNA genome, 13.0–18.5 kb in size. A wide variation in genome size and organization is typical for species in this genus. The natural transmission of ampeloviruses is by pseudococcid mealybugs and soft scale insects (**Table 2**). The type species of the genus *Ampelovirus* is *Grapevine leafroll-associated virus 3* (GLRaV-3).

The genus *Crinivirus* comprises 13 species transmitted by whiteflies. Virions usually have two modal lengths (650–850 and 700–900 nm) and a bipartite positive-sense, single stranded RNA genome with a size ranging from 7801 to 9127 nt (RNA-1) and from 7903 to 8530 nt (RNA-2) (**Table 2**). The type species of the genus *Crinivirus* is *Lettuce infectious yellows virus* (LIYV). Noteworthy, Potato yellow vein virus (PYVV) has a tripartite positive-sense, single-stranded RNA genome of 8035 nt (RNA-1), 5339 nt (RNA-2) and 3892 nt (RNA-3) in size (**Table 2**).

The genus *Velarivirus* comprises seven species with particles ranging from 1500 to 1700 nm in length, a monopartite, positive-sense, single-stranded RNA genome, 16–16.9 kb in size, and no known hemipteran vectors (**Table 2**). The type species of the genus *Velarivirus* is *Grapevine leafroll-associated virus 7* (GLRaV-7).

Genome Organization

The 5' end of the genome of viruses in the family *Closteroviridae* is likely capped, and the 3' end is not polyadenylated and does not possess a tRNA-like structure. The genome organization is conserved among species in the family although the number and relative

position of the different open reading frames (ORFs) differ between genera and/or individual viral species. However, the dual gene module ORF1a–ORF1b at the 5′ end of the genomic RNA invariably encodes the replication-associated proteins with conserved domains for a papain-like cysteine protease (L-Pro), a methyl-transferase (MET), a helicase (HEL), and an RNA-dependent RNA polymerase (RdRp). Downstream ORFs form a conserved five-gene module with few modifications among most members of the family. This quintuple gene module codes for, in the 5′→3′ direction, a 6K small hydrophobic protein, the HSP70h, a ~60 kDa protein, a CP, and a CPm.

The HSP70h and the ~60 kDa proteins are integral virion components present in all the sequenced members of the family. The functions postulated for HSP70h are mediation of cell-to-cell movement through plasmodesmata, involvement in the assembly of multi-subunit complexes for genome replication and/or sub-genomic RNAs synthesis, as well as assembly of virus particles. The ~60 kDa protein is required for incorporation of both HSP70h and CPm to virion heads. In general, CP and CPm show a significant degree of sequence conservation for each species in the family and the duplicate copies probably retain the general spatial folding and some crucial properties of the CPs. Noteworthy, a group of ampeloviruses [e.g., Grapevine leafroll-associated virus 4 (GLRaV-4) and related strains, Pineapple mealybug wilt-associated virus 1 (PMWaV-1) and Pineapple mealybug wilt-associated virus 3 (PMWaV-3), Air potato ampelovirus 1 (AiPoV-1), and Plum bark necrosis stem pitting-associated virus (PBNSPaV)] with the smallest genome in the family does not appear to possess a CPm; and grapevine leafroll-associated virus 1 (GLRaV-1) carries two copies of CPm.

The genome expression strategy of viruses in the family *Closteroviridae* is based on: (1) proteolytic processing of the polyprotein encoded by ORF1a; (2) +1 ribosomal frameshift for the expression of the RdRp domain encoded by ORF1b; and (3) expression of the downstream ORFs via the formation of a nested set of 3′ co-terminal sub-genomic RNAs (sgRNAs). Analysis of double stranded (ds) RNAs in infected plant tissue reveals very complex and variable patterns among species of the family, reflecting the different numbers and sizes of ORFs present in individual genomes and, in some cases, the existence of defective RNAs. The largest dsRNA is usually the replicative form of the entire genome and sgRNAs generate a range of smaller dsRNAs.

For species in the genus *Closterovirus* (Table 3), the order of the CP and CPm ORFs is reversed compared to that of species in the genera *Ampelovirus*, *Crinivirus*, and *Velarivirus*. BYV contains eight ORFs flanked by 5′ and 3′ untranslated (UTRs) of 107 and 181 nt, respectively, including an extra ORF (ORF2) encoding a 30 kDa polypeptide with no similarity to any other protein in databases (Fig. 2). Citrus tristeza virus (CTV) has 12 ORFs and UTRs of 107 nt at the 5′ end and 275 nt at the 3′ end. It differs from the BYV genome in having two L-Pro domains in ORF1a [so does Grapevine leafroll-associated virus 2 (GLRaV-2)], and two extra 3′ proximal ORFs (ORF9 and ORF11). The genome organization of Beet yellows stunt virus (BYSV) is intermediate between that of BYV and CTV with 10 ORFs and a 3′UTR 241 nt in size, suggesting that these three viruses might represent three distinct stages in the evolution of closteroviruses. Non-structural proteins common to all members of the genus are: (1) a large polypeptide (over 300 kDa) containing the conserved domains of L-Pro, MET, and HEL; (2) a ~50 kDa protein with all sequence motifs of viral RdRp; (3) a 6 kDa hydrophobic protein with membrane-binding properties; (4) the homolog of the cellular HSP70; and (5) a 55–64 kDa product, referred to as the ~60 kDa protein. Some of the structural and non-structural proteins function as suppressors of the RNA silencing plant defense mechanisms. For instance, CP, p20 and p23 proteins of CTV have suppressor activity, much the same as the homologs of p21 of BYSV, BYV, and GLRaV-2. Silencing suppressors contribute to the accumulation of virus particles and are important determinants of pathogenesis. The CTV p23 is a unique protein in the family with a nucleolar localization.

For species in the genus *Ampelovirus* (Table 3), Grapevine leafroll-associated virus 3 (GLRaV-3) has the largest genome of the family with 18,498 nt and 12 ORFs coding for the replication related proteins (ORFs 1a and 1b), two small hydrophobic proteins (6 kDa), the HSP70h, the ~60 kDa protein, CP, CPm, and five additional proteins of 21, 20, 20, 4, and 7 kDa in size, respectively (Fig. 3). The 5′ and 3′ UTRs are 737 and 277 nt in size, respectively. GLRaV-3 is a sub-group I ampelovirus. Subgroup II species in the genus have only seven ORFs and lack the CPm. For example, PMWaV-1 has a genome 13,071 nt in size, beginning with a 535 nt UTR at the 5′ end, followed by the ORFs expressing the replication related proteins, a 6 kDa hydrophobic protein, the HSP70h, the ~60 kDa protein, the CP, and a 24 kDa protein, respectively. A UTR 132 nt in size terminates the genome at the 3′ end. Structural and non-structural proteins are similar in type and function to those reported for the genus *Closterovirus* although ORF1a harbors, in addition to a L-Pro, an AlkB domain for RNA demethylation.

For species in the genus *Crinivirus* (Table 3), the genome is divided between two linear, positive sense, single-stranded RNAs (Fig. 4) although PYV is an exception with a tripartite genome. All RNA molecules are needed for infectivity and are separately encapsidated. RNA1 of LIYV contains three ORFs, i.e., the ORF1a–ORF1b complex coding for the replication-related proteins, plus a 3′-most ORF coding a 34 kDa protein with no similarity to any protein in databases. This ORF is similar in size and location to ORF2 of CTV and BYSV although the respective expression products are not related. RNA1 has 5′ and 3′UTRs of 97 and 219 nt, respectively. RNA2 has seven ORFs flanked by a 5′UTR of 326 nt and a 3′UTR of 187 nt. RNA2 contains the quintuple gene module, which, however, differs from that of members of the genera *Closterovirus*, *Ampelovirus*, and *Velarivirus* by the insertion of an extra gene (ORF4, p9-10) upstream of the CP gene. The ultimate ORF at the 3′ end of RNA2 of LIYV codes p26; this protein induces plasmalemma deposits, is localized in plasmodesmata, and is required for LIYV systemic plant infection. For PYV, RNA1 (8035 nt in size) is composed of three ORFs, i.e., the ORF1a–ORF1b complex and a 7 kDa hydrophobic protein containing a potential transmembrane helix; RNA2 (5339 nt in size) comprises five predicted ORFs that encode the HSP70h, a 7 kDa protein similar to a comparable protein of cucurbit yellow stunting disorder virus (CYSDV), the ~60 kDa protein, a 9.8 kDa product with no significant similarity to any other sequence in database, and the 28.2 kDa putative CP; and RNA-3 (3892 nt) has three potential ORFs coding for a protein 4 kDa in size with no counterpart with other proteins in the family and no significant sequence homology in databases, the 77.5 kDa CPm, and a 26.4 kDa protein present in other members of the genus. Sweet potato chlorotic stunt virus (SPCSV) and Tomato chlorosis virus (ToCV) have a particularly large CPm (75–80 kDa) compared to LIYV (53 kDa). Both genomic

^aPartial sequence.

RNAs of ToCV encode RNA silencing suppressors, e.g., the p22 protein in RNA1, and CP and CPM in RNA2. The p25 protein of CYSDV, a viral RNase III, and the p22 gene present in a few isolates of SPCSV also have RNA silencing suppressor activity.

For the virus species in the genus *Velarivirus* (Table 3), Little cherry virus 1 (LChV-1) has the largest genome of the genus with 16,934 nt and nine ORFs coding for the replication associated proteins (ORF1a with a L-Pro, a MET and a HEL; and ORF1b with a

Fig. 2 Genome organization and strategy of replication of species in the genus *Closterovirus* with the relative position of the open reading frames, their expression products, and 3' nested sub-genomic RNAs (sgRNAs). Information on genomic organization and sgRNAs is provided for Beet yellows virus (BYV), the type species of the genus *Closterovirus*: UTR, untranslated region; L-Pro, leader papain-like cysteine proteinase; MET, methyltransferase; CR-1, central region 1; CR-2, central region 2; HEL, helicase; RdRp, RNA-dependent RNA polymerase; HSP70h, heat shock protein 70 homolog; ~60 kDa protein; CPm, minor coat protein; CP, coat protein. The five boxes under cell-to-cell movement represent the quintuple gene module conserved among most closteroviruses. Information on proteolytic processing of the polyprotein precursors is provided for Citrus tristeza virus (CTV).

RdRp), a small hydrophobic protein (4–8 kDa) with a transmembrane domain, the HSP70h, the ~60 kDa protein, CP, CPm, and two additional proteins 25 and 27 kDa in size (Fig. 5) (ICTV, see “Relevant Websites Section”). The genome of GLRaV-7 is 16,496 nt in size and has nine ORFs encoding structural and non-structural proteins similar in type and function to those of LChV-1.

Phylogenetic relationships based on HSP70h aa sequences reveal the grouping of species into four distinct genera with a few species unassigned to the family (Fig. 6). Similar trees are obtained when analyzing phylogenetic relationships based on CP or RdRp aa sequences. The genic diversity of species in the family *Closteroviridae* is primarily influenced by (1) strong negative selection for some viruses, (2) co-infection by genetically similar sequence variants in distant geographic regions, likely as a result of the extensive exchange of infected propagative planting material, (3) recombination between divergent sequence variants, (4) preferential accumulation of certain virus strains in relation to mixed infections, and (5) positive selection of sequence variants due to host change or transmission by insect vectors.

From an evolutionary point of view, viruses in the family *Closteroviridae* represent a monophyletic virus lineage that might have evolved from a smaller filamentous virus when higher plants have differentiated. This progenitor virus is hypothesized to be composed of three genes encoding replication-associated proteins, a protein (p6) with affinity for cell membranes, and a single CP, and then to have acquired the HSP70h and a ~60 kDa protein derived from a fusion of two domains, a N-terminal domain of unknown evolutionary provenance, and a duplicated CP domain. Under the pressure of additional modular evolutionary events, i.e., duplication of the CP gene, acquisition of diverse suppressors of RNA silencing and of additional genes acquired via horizontal gene transfer (e.g., papain-like cysteine proteinase and AlkB domains), this family ancestor gave rise to the progenitors of the four extant genera of the family. Species in the genus *Crinivirus* differentiated further by splitting their genome in two or three components.

Based on their extreme genomic stability, a few species in the family *Closteroviridae* have been engineered as gene expression and RNA interference vectors. For instance, BYV, LIYV, CTV, GLRaV-2, and GLRaV-3 have been engineered as vectors by elegantly inserting a heterologous sgRNA promoter into an optimal genomic location to drive the expression of the green fluorescence protein reporter, or silence host genes such as the phytoene desaturase via inverted-repeat sequences. The most notable success of a closterovirus-derived vector has been achieved with GLRaV-2.

Fig. 3 Genome organization of Grapevine leafroll-associated virus 3 (GLRaV-3), the type species of the genus *Ampelovirus*, showing the relative position of the open reading frames and their expression products: UTR, untranslated region; L-Pro, leader papain-like protease; MET, methyltransferase; AlkB, alpha-ketoglutarate-dependent hydroxylase domain; HEL, helicase; RdRp, RNA-dependent RNA polymerase; HSP70h, heat shock protein 70 homolog; ~60 kDa protein; CP, coat protein; CPm, minor coat protein. The predicted sub-genomic RNAs (sgRNAs) are indicated below the genome map. Putative sgRNAs are indicated by dashed lines.

Infectious Cycle

Positive-sense RNA viruses, such as members of the family *Closteroviridae*, express their replication-associated proteins in infected plant cells following translation of the genomic RNAs. The replication complex then initiates the synthesis of complementary RNA strand while remodeling host membranes, thus creating cytoplasmic compartments that are referred to as virus factories. Such compartmentalization secures RNA replication from the action of nucleases and pattern recognition receptors that trigger host innate immunity responses while providing opportunities for exchange with the cytoplasm for the export of, for instance, newly synthesized genomic and sub-genomic RNAs.

The 3'UTR of the genomic RNA of species in the family *Closteroviridae*, particularly CTV, is highly conserved and contains several hairpin structures and a putative pseudoknot that is essential for replication, while the 5'UTR is variable but adopts a conserve secondary structure that is important for replication and proper encapsidation of the viral RNA. Replication occurs in the cytoplasm, possibly in association with endoplasmic reticulum-derived membranous vesicles and vesiculated mitochondria. Virus encoded polyproteins 1a and 1b direct membrane remodeling and formation of multi-vesicular replication factories. Polyprotein 1a of BYV contains a variable central region (CR) between the MTR and HEL domains of which a stretch (aa 1368–1432) induces the formation of 1-μm mobile globules originating from endoplasmic reticulum membranes. Part of the CR is conserved in all members of the genus *Closterovirus* and contains a predicted amphipathic helix (aa 1368–1385). This region may be involved in the biogenesis of closterovirus replication factories.

Ultrastructural modifications arise by membrane proliferation, degeneration and vesiculation of mitochondria, and formation of inclusion bodies. These are made up of aggregates of virions or membranous vesicles, or a combination of the two. Virions accumulate in conspicuous cross-banded fibrous masses or, more typically, in more or less loose bundles intermingled with single or clustered membranous vesicles. The vesicles contain a fibrillar network and derive either from the endoplasmic reticulum, or from peripheral vesiculation of mitochondria.

Fig. 4 Genome organization of Lettuce infectious yellows virus (LIYV), the type species of the genus *Crinivirus*, showing the relative position of the open reading frames and their expression products: UTR, untranslated region; L-Pro, papain-like protease; MET, methyltransferase; HEL, helicase; RdRp, RNA-dependent RNA polymerase; HSP70h, heat shock protein 70 homolog; ~60 kDa protein; CP, coat protein; CPm, minor coat protein.

Fig. 5 Genome organization of Grapevine leafroll-associated virus 7 (GLRaV-7), the type species of the genus *Velarivirus*, showing the relative position of the open reading frames and their expression products: UTR, untranslated region; L-Pro, papain-like protease; MET, methyltransferase; HEL, helicase; RdRp, RNA-dependent RNA polymerase; HSP70h, heat shock protein 70 homolog; ~60 kDa protein; CP, coat protein; CPm, minor coat protein.

For GLRaV-3, putative 3' co-terminal sgRNAs are differentially expressed with four of them accumulating at high levels (CP, p20A, p20B, p21), two at intermediate levels (p4 and p7), and others at low levels (CPm, p55, HSP70h, and p5). This suggests temporal and quantitative regulation of sgRNAs transcription during plant infection. Each of these sgRNAs serves as a monocistronic messenger for translation of the corresponding 5'-proximal ORF. The 5' transcriptional start sites were determined for several GLRaV-3 sgRNAs. Additionally, the leader sequence of sgRNAs is variable in size and does not share conserved motifs.

For LIYV, the replication of both genomic RNAs is asynchronous as RNA1 genomic and sgRNAs accumulate before significant accumulation of RNA2 can be detected, suggesting that RNA1 likely replicates in *cis* while RNA2 replicates in *trans*. Knockout mutation studies showed that the single-stranded RNA-binding protein p34 that is encoded by RNA1 is a *trans* enhancer of RNA2 replication.

Epidemiology

Transmission of viruses in the family *Closteroviridae* by natural vectors is semi-persistent regardless of the type of vector, i.e., aphids (genus *Closterovirus*), whiteflies (genus *Crinivirus*), and pseudococcid mealybugs and soft scale insects (genus *Ampelovirus*). No insect vector is known for viruses in the genus *Velarivirus*. Additionally, some species in the family, particularly velariviruses, can be transmitted through dodder (*Cuscuta* spp.). Transmission through seeds has not been documented. Only a few species of the genus *Closterovirus* (CTV, GLRaV-2, BYV) are transmissible by mechanical inoculation to herbaceous hosts, though with difficulty, but none of the viruses in the genera *Ampelovirus*, *Crinivirus* and *Velarivirus* are mechanically transmissible.

Viruses in the family *Closteroviridae* that infect vegetatively propagated hosts are transmitted by grafting and, thus, disseminated over long distances with propagating material that is not adequately screened for their presence. The natural and experimental host ranges are usually restricted, except for a few members of the genus *Crinivirus*. Similarly, the geographical

Fig. 6 Maximum likelihood phylogenetic tree showing the relationships among recognized members of the family *Closteroviridae* based on an alignment of the complete amino acid sequence of the heat shock protein 70 homolog using MUSCLE. The maximum likelihood tree was inferred using RAxML in the T-REX web server. Distances are proportional to branch lengths and the bar represents the genetic distance. The heat shock protein 70 from *Arabidopsis thaliana* (AEE75218) was used as outgroup. The GenBank accession number used for each virus is as follows: Actinidia virus 1 (AcV-1, KX857665), Air potato ampelovirus 1 (AiPV-1, MH206615), arracacha virus 1 (AV-1, MG919988), Blackcurrant closterovirus 1 (BCCV1, MH267701), Bean yellow disorder virus (BYDV, EU191904), Beet pseudoyellows virus (BPYV, AY330918), Beet yellow stunt virus (BSYV, U51931), Beet yellows virus (BYV, AF056575), Blackberry vein banding-associated virus (BVBaV, KC904540), Blueberry virus A (BVA, AB733585), Carnation necrotic fleck virus (CVFV, GU234166), Carrot yellow leaf virus (CYLV, FJ869862), Citrus tristeza virus (CTV, U16304), Cordyline virus 1 (CoV-1, HM588723), Cordyline virus 2 (CoV-2, JQ599282), Cordyline virus 3 (CoV-3, JQ599283), Cordyline virus 4 (CoV-4, JQ599284), Cucurbit yellow stunting disorder virus (CYSDV, AY242077), Diodia vein chlorosis virus (DVCV, CQ376201), Fig leaf mottle-associated virus 2 (FLMaV-2, FJ473383), Fig mild mottle-associated virus (FMMaV, FJ611959), Grapevine leafroll-associated virus 1 (GLRaV-1, JQ023131), Grapevine leafroll-associated virus 2 (GLRaV-2, JX513891), Grapevine leafroll-associated virus 3 (GLRaV-3, EU259806), Grapevine leafroll-associated virus 4 (GLRaV-4, FJ467503), Grapevine leafroll-associated virus 7 (GLRaV-7, HE588185), Grapevine leafroll-associated virus 13 (GLRaV-13, LC052212), Lettuce chlorosis virus (LCV, FJ380118), Lettuce infectious yellows virus (LIYV, U15440), Little cherry virus 1 (LChV-1, EU715989), Little cherry virus 2 (LChV-2, AF531505), Mint vein banding-associated virus (MVBaV, KJ572575), Mint virus 1 (MV-1, AY792620), Palm velarivirus 1 (ArPV1, KR349464), Persimmon virus B (PeBV, AB923924), Pineapple mealybug wilt-associated 1 (PMWaV-1, AF414119), Pineapple mealybug wilt-associated 2 (PMWaV-2, AF283103), Pineapple mealybug wilt-associated 3 (PMWaV-3, DQ399259), Pistachio ampelovirus A (PAVA, MF198462), Plum bark necrosis stem pitting-associated virus (PBNSPaV, EF546442), Raspberry leaf mottle virus (RLMoV, DQ357218), Rehmannia virus 1 (ReV-1, MH033657), Rose leaf rosette-associated virus (RLRaV, KJ7488003), Strawberry chlorotic fleck-associated virus (SCFaV, DQ860839), Potato yellow vein virus (PYVV, AJ557128), Strawberry pallidosis-associated virus (SPaV, AY488138), Sweet potato chlorotic stunt virus (SPCSV, AJ428554), Tetterwort vein chlorosis virus (TwVSV, KR002687), Tobacco virus 1 (TV1, KT203917), Tomato chlorosis virus (ToCV, AY903447), and Tomato infectious chlorosis virus (TICV, FJ815440).

distribution of viruses varies from restricted [Grapevine leafroll-associated virus 13 (GLRaV-13), Mint virus 1 (MV-1), Tobacco virus 1 (TV1)] to widespread (CTV, GLRaV-2, GLRaV-3, BYV).

The range of vectors for species in the genus *Closterovirus* varies from rather wide to restricted. For example, BYV is transmitted by at least 23 aphid species (*Myzus persicae* and *Aphis fabae* being the main natural vectors), CTV by seven species (*Toxoptera citricida* and *Aphis gossypii* being the most efficient vectors), MV-1 by a single aphid species while GLRaV-2 does not have any known vectors. Recent studies of specific interactions between CTV and its aphid vector, *Toxoptera citricida*, indicate the cibarium of the

aphid foregut as the virus retention site, and the critical role of a protein-carbohydrate complex for transmission with three viral proteins, i.e., the CPm, p61, and p65, binding to sugar moieties on the surface of the foregut.

For species in the genus *Ampelovirus*, the range of vectors varies from large to narrow. For instance, GLRaV-1 is transmitted by species of several genera of pseudococcid mealybugs (*Heliococcus*, *Phenacoccus*, *Pseudococcus*) and soft scale insects (*Pulvinaria*, *Neopulvinaria* and *Parthenolecanium*). Similarly, GLRaV-3 is transmitted by a wide range of pseudococcid mealybugs (*Planococcus*, *Pseudococcus*, *Heliococcus*, *Phenacoccus*) and soft scale insects (*Pulvinaria*, *Neopulvinaria*, *Parthenolecanium*, *Coccus*, *Saissetia*, *Parasaissetia*, *Ceroplastes*). To the contrary, vectors of PMWaV-1, PMWaV-2 and PMWaV-3 are two species of the genus *Dysmicoccus*, and LChV-2 is transmitted by *Phenacoccus aceris*.

Species in the genus *Crinivirus* are transmitted by whiteflies of the genera *Trialeurodes* and *Bemisia*. The specificity of transmission has been used for species differentiation. For example, viruses of group 1 [PYV, Blackberry yellow vein-associated virus (BYVaV), Beet pseudoyellows virus (BPYV) and Strawberry pallidosis-associated virus (SpaV)] are transmitted by *T. vaporariorum*, viruses of group 2 [ToCV, SPCSV, CYSDV, and Bean yellow disorder virus (BYDV)] by *B. tabaci*, whereas one of the viruses of group 3 is transmitted by *B. tabaci* (LIYV) and the other by *T. vaporariorum* (TICV). These three groups are sustained by comparative phylogenetic analyses of RdRp aa sequences.

Disease Symptoms

Viruses in the family *Closteroviridae* infect fruit, vegetable, tuberous, and berry crops, as well as herbs, flowering plants, shrubs, and weeds. They cause foliar discolorations (chlorosis, discoloration, or reddening) and rolling (Fig. 7), stem pitting and grooving on the woody cylinder of woody hosts, stunting, or symptomless infections. Disease symptoms also include small and late ripening fruits.

Pathogenesis

Plant infection by species in the family *Closteroviridae* is systemic but virions are usually found in the phloem (sieve tubes, companion cells and parenchyma), and only occasionally in the mesophyll and epidermis. Virus-host interactions have been

Fig. 7 Disease symptoms caused by selected viruses of the family *Closteroviridae* on their natural host. (A) Downward rolling and reddening of the leaf blade of *Vitis vinifera* cv. Pinot noir infected with Grapevine leafroll-associated virus 3 from the genus *Ampelovirus*, (B) Aerial view of declining and dead citrus trees grafted onto the sour orange rootstock in a grove infected with Citrus tristeza virus from the genus *Closterovirus*. Infected trees show necrosis at the graft union with reduced carbohydrate movement into the roots, and leaves fall off (courtesy of W.O. Dawson, University of Florida, USA), (C) Interveinal discoloration of melon leaves infected by Cucurbit yellow stunting disorder virus from the genus *Crinivirus* (courtesy of W. Wintermantel, USDA-ARS, Salinas, California, USA), (D) Discoloration of tomato leaves infected by Tomato chlorosis virus from the genus *Crinivirus* (courtesy of W. Wintermantel, USDA-ARS, Salinas, California, USA), and (E) Tomato infectious chlorosis virus from the genus *Crinivirus* (courtesy of W. Wintermantel, USDA-ARS, Salinas, California, USA). Note the similarities of symptomatology caused by ToCV and TICV, and by magnesium deficiency.

extensively studied for CTV. Protein p23 is a multifunctional RNA-binding protein with a putative zinc finger domain that accumulates in the nucleolus and plasmodesmata. It regulates the asymmetric balance of plus and minus RNA strands during replication, induces disease symptoms similar to those caused by CTV infection in certain hosts, and enhances systemic infection, and virus accumulation. Recently, it was shown that CTV uses the cytosolic glyceraldehyde 3-phosphate dehydrogenase via interaction with p23 to facilitate infection. In addition, p23 like p25 and p20 is a suppressor of RNA silencing. Proteins p33, p18, and p13 are dispensable for systemic infection of certain hosts, and involved in stem pitting disease symptoms.

Diagnosis

The visual identification of disease symptoms incited by viruses in the family *Closteroviridae* can be challenging due to confounding factors such as asymptomatic infections, virus co-infections, or similarities with nutritional deficiencies. Several techniques have been developed and applied to diagnose closteroviruses, including biological assays, serological assays, nucleic acid-based methods, and large-scale sequencing.

Biological indexing consists of chip budding a candidate plant to a disease susceptible, indicator plant. The indicator plant with the newly grafted material is then observed for the development of disease symptoms. This approach is labor intensive, time consuming, costly, and often not very robust. Biological assays are progressively replaced by more powerful diagnostic assay that identify viruses rather than diseases.

Serological diagnostic techniques such as enzyme-linked immunosorbent assays have been developed for simple, cost-effective and high-throughput testing. Although virion proteins are often moderately antigenic, serological reagents are available for many viruses in the family *Closteroviridae*, and most species within genera are serologically unrelated or distantly related to one another, for instance, GLRaV-1 and GLRaV-3, or GLRaV-1 and GLRaV-13, but no intergeneric serological relationship has been detected.

Nucleic acid-based diagnostic methods are increasingly used for the detection of closteroviruses. Such assays include reverse transcription (RT) polymerase chain reaction (PCR) and variations thereof (immunocapture-RT-PCR, spot RT-PCR, RT-qPCR), loop-mediated amplification of nucleic acid, and oligonucleotide microarrays. These assays are often more robust than serological assays. More recently, large scale sequencing is increasingly used for discovery of new viruses, including closteroviruses, and for an unbiased diagnosis of a virome in a plant sample without any prior knowledge of the pathogens present. This technology should facilitate the safe and rapid exchange of propagative plant material.

Treatment

Management of diseases caused by viruses in the family *Closteroviridae* is challenging, due mainly to the absence of curative practices. Strategies to mitigate the impact of viruses rely almost exclusively on preventive approaches.

Prevention

Screening nursery stocks for viruses is critical for the production of clean planting material and the establishment of clean production fields. Planting material derived from virus-tested nursery stocks minimizes virus incidence. Technological advances that enable the efficient, rapid identification and removal of virus-infected stocks facilitate disease management tactics. Additionally, reducing disease inoculum via, for instance, roguing, is critical to limit disease spread, especially in perennial crops.

Glossary

Viral protein genome-linked A protein covalently attached to the 5' end of positive strand viral RNA and acting as a primer during RNA synthesis.

Virus re-assortment The mixing of the genome segments of a virus into new combinations.

Virus replication complexes Intracellular complexes formed by association with intracellular membranes that are sites for stages in the replication cycle of a virus.

β -barrel Beta-sheet composed of tandem repeats forming a closed structure.

Introduction

The genera *Comovirus* and *Fabavirus* are non-enveloped plant viruses that are classified within the family *Secoviridae*. They typically cause mottle or mosaic symptoms on susceptible hosts and are characterized by having a bipartite RNA genome with the individual components separately encapsidated in isometric particles (Fig. 1). Though having similar genetic and particle structures, the two genera are distinguished on the basis of their insect vectors.

Taxonomy and Classification

The genus *Comovirus* is named after the type species, *Cowpea mosaic virus* (CPMV). The genus *Fabavirus* derives its name from the host species (*Vicia faba*) from which the first member of the genus, *Broad bean wilt virus* (BBWV), was originally isolated as the causative agent of vascular wilt symptoms. At present, 15 and 7 distinct virus species are recognized by the International Committee for the Taxonomy of Viruses (ICTV) as being members of the genus *Comovirus* and *Fabavirus*, respectively (Table 1). Together with the genus *Nepovirus*, they are classified in the subfamily *Comovirinae* within the family *Secoviridae*. Comoviruses and fabaviruses are insect-transmitted by beetles and aphids, respectively, while nepoviruses are nematode-transmitted. The relationship between members of the two genera and their relationship to other members of the family *Secoviridae* is shown in (Fig. 2).

In several instances, individual comoviruses and fabaviruses have been shown to exist in several different strains. For example, three distinct strains of *Red Clover mottle virus* (RCMV), termed -S, -N and -O, have been described. In the case of *Bean pod mottle virus* (BPMV) at least two distinct strains have been reported and these can reassort. Detailed molecular characterization of BPMV reassortants has revealed the presence of strains that are diploid for RNA1 and haploid for RNA2. The fabaviruses, BBWV-1 and BBWV-2 were originally classified as strains of the same species but are now considered to be distinct species.

Physical Properties of Viral Particles

The yields of comovirus particles from infected tissue are typically higher than those of fabaviruses, particles of which have a tendency to aggregate on purification. The thermal inactivation point of viral particles in plant sap is in the range 60–75°C and the particles have a longevity in sap of between 2 and 112 days at room temperature.

Comovirus and fabavirus preparations consist of non-enveloped isometric particles, approximately 30 nm in diameter, which can be separated into three components designated top (T), middle (M) and bottom (B) by centrifugation on sucrose density

Fig. 2 Phylogenetic relationships within the family *Secoviridae*. The comoviruses and fabaviruses form two distinct branches within the subfamily *Comovirinae*, which includes the nepoviruses. Alignment figure courtesy of Prof. J. Thompson.

gradients (**Fig. 1(B)**). The exact sedimentation coefficients of the components vary slightly with the virus being analyzed but are typically in the range 50-60S for T, 90-100S for M and 110-120S for B components. The three components have identical protein compositions, containing 60 copies each of a large (L) and small (S) coat protein (CP). The sizes of the two proteins vary depending on the virus but lie in the ranges 37-49 kDa for the L protein and 18-26 kDa for the S protein. The difference between the three centrifugal components is in their RNA contents. Top components are devoid of RNA, while middle and bottom components each contain single molecules of RNA of approximately 3-4 kb and 6 kb, respectively. The two RNA molecules were originally termed middle (M) and bottom (B) component RNA after the nucleoprotein component from which they were isolated but are now termed RNA2 and RNA1, respectively (**Fig. 3(A)**).

Because of their differing RNA contents, the three components of comoviruses and fabaviruses also differ in density and can hence be separated by isopycnic centrifugation. Generally, T, M and B components have densities of approximately 1.29, 1.40 and 1.41 g ml⁻¹ respectively. However, the pattern obtained is often more complex than that seen with sucrose gradients and depends on the precise conditions used and virus being examined. For example, while BPMV gives the expected three components when centrifuged on cesium chloride gradients under a wide range of conditions, the bottom component of CPMV can be resolved into two forms of differing density under alkaline conditions.

Preparations of comoviruses are often not only centrifugally heterogeneous but can also be separated in two forms, fast and slow, electrophoretically. Both electrophoretic forms contain all three centrifugal components. The proportion of the two electrophoretic forms in a given viral preparation varies both with the time after infection at which the virus was isolated and the age of the preparation itself. Conversion of one form to the other is caused by loss of amino acids from the C terminus of the S protein. In the case of CPMV, this segment has been shown to be critical for virus assembly, and structural studies on Broad bean stain virus (BBSV) suggest that comoviruses share a common assembly mechanism. Though not studied extensively, it is likely that fabavirus particles also undergo a similar cleavage of the S protein.

In a number of instances, comovirus particles have been shown to contain polyamines, particularly spermidine. Such polyamines are believed to have a role in the neutralization of the negative charges of the RNA within the particles. It is the exchange of such polyamines for cesium ions that leads to the two forms of bottom component of CPMV seen under alkaline conditions.

Fig. 3 Molecular details of comoviruses and fabaviruses. (a) Organization of the two single-stranded RNA molecules that comprise the genome. Both RNAs have a VPg (red circle) linked to their 5' ends and both are polyadenylated. RNA1 contains a single ORF that is processed by the 24K protease (Pro) to give the viral proteins required for RNA replication. The functions of the individual processed products are indicated. RNA2 encodes the structural CPs, Large (L) and Small (S) as well as the MP required for the movement of CPMV virions from cell-to-cell. The solid line indicates translation from the upstream initiation codon that results in an N-terminal extension to the MP, while translation from the downstream initiation codon indicated by the dotted line results in the MP. (b) Arrangement of the CP subunits of comoviruses and fabaviruses. The asymmetric unit consists of one single-domain S subunit (blue) and one two-domain L subunit (green and red), 60 copies of which are arranged with icosahedral symmetry to form a pseudo $T = 3$ ($P = 3$) capsid. (c) Ribbon diagram of the asymmetric unit, showing β -barrel structure of the L (green and red) and S (blue) subunits.

Viral Structure

X-ray crystallographic and cryo-EM studies on CPMV, BPMV, RCMV and BBSV have provided a detailed picture of the arrangement of the two viral CPs in the three-dimensional structure of comoviruses. Though, at the time of writing, there is no detailed structure of a fabavirus available, it is highly probable that their overall architecture is very similar. Comovirus virions are icosahedrally symmetrical, with 12 axes of fivefold and 20 axes of threefold symmetry and resemble a classic $T = 3$ particle (**Fig. 3(B)**). The two CPs taken together consist of three distinct β -barrel domains, two being derived from the L and one from the S protein. Thus, in common with the $T=3$ viruses, each CPMV particle is made up of 180 β -barrel structures. The S protein, with its single domain, is found at the fivefold symmetry axes and therefore occupies a position analogous to that of the A type subunits in $T = 3$ particles (**Fig. 3(c)**). The N- and C-terminal domains of the L protein occur at the threefold axes and occupy the positions equivalent to those of the C and B type subunits of a $T = 3$ particle respectively. Comovirus (and, by inference, fabavirus) capsids are also structurally homologous to those of the picornaviruses, with the N- and C-terminal domains of the L protein being equivalent to viral protein VP2 and viral protein VP3, respectively, and the S protein being equivalent to viral protein VP1. In the case of BPMV, ordered segments of RNA2 could be seen in the crystallographic structure of M components. RNA has also been detected in the cryo-EM structures of the M and B components of CPMV and in an unfractionated mixture of BBSV.

Genome Structure

The genomes of both comoviruses and fabaviruses consist of the two RNAs (RNA1 and RNA2) encapsidated in bottom and middle components. Both RNA molecules are positive-sense and both are required for an infection of whole plants. In the case of CPMV, RNA1 is capable of independent replication in individual plant cells but this results in the establishment of gene silencing in the absence of RNA2, which encodes a suppressor of gene silencing. Both genomic RNAs have a small basic protein (VPg) covalently linked to their 5' termini and are polyadenylated. The VPg is linked to the viral RNA via the β -hydroxyl group of its N-terminal serine residue. The VPg is not required for the viral RNAs to be infectious.

The complete nt sequences of both RNAs of most comoviruses and fabaviruses have been determined (**Table 1**); in addition, several partial sequences are also available. The two genomic RNAs of a given virus have no sequence homology apart from at the 5' and 3' termini. Full-length infectious cDNA clones of several viruses have been constructed (**Table 1**), allowing the genomes of these viruses to be manipulated.

Expression of the Viral Genome

Both genomic RNAs contain a single long open reading frame (ORF) which occupies over 80% of the length of the RNA. A combination of *in vitro* translation and protoplast studies has unraveled the basic mechanism of expression of the genomic RNAs

of CPMV, the type species of the genus *Comovirus*. More limited studies on other members of the group suggest that the mode of gene expression deduced for CPMV is applicable to all members of the genera.

Both RNAs of the comoviruses and fabaviruses are expressed through the synthesis and subsequent cleavage of large precursor polyproteins. On RNA1, initiation of translation occurs at the first AUG encountered on the sequence and results in the synthesis of a protein of approximately 200 kDa. This initial product undergoes rapid co-translational autoproteolysis to give proteins with apparent sizes of 32 and 170 kDa (the 32 and 170K proteins). The 170K protein undergoes further cleavages to give the range of virus-specific proteins, the functions of which are indicated in Fig. 2(A). The proteolysis of the polyprotein is catalysed by the region marked Pro in Fig. 2(A).

Initiation of translation of RNA2 occurs at two different positions on the RNA and results in the synthesis of two carboxy coterminal proteins. This double initiation phenomenon, which occurs as a result of “leaky scanning” of two in-frame AUG codons, is found with the RNA2 molecules of all comoviruses and fabaviruses. The distance between the two initiation codons varies significantly between different viruses, as does the sequence of the encoded aa. Both RNA2-encoded primary translation products are cleaved by the RNA1-encoded Pro to give the movement protein (MP) and a version with an N-terminal extension as well as the two viral CPs, L and S. Processing of the RNA2-encoded polyproteins at the site between MP and L CP also requires the presence of the protease cofactor (ProC) as well as Pro.

Functions of the Viral Proteins

Functions have been ascribed to most of the regions of the polyproteins encoded by both RNA1 and RNA2 based on extensive investigations with CPMV. Far less information is available for other comoviruses and fabaviruses, with what little that is available indicating that the analyses conducted with CPMV are generally applicable. Therefore, the reader is referred to the article on CPMV for a detailed description of the functions of the viral proteins.

Relationships With Other Viruses

Together with the genus *Nepovirus*, the genera *Comovirus* and *Fabavirus* are grouped within the subfamily *Comovirinae*, in the family *Secoviridae*. Consideration of genome structure and organization, translational strategy and aa homologies between the virus-encoded proteins has led to the family *Secoviridae* being grouped with the family *Picornaviridae*, within the order *Picornavirales*. Members of this order are all non-enveloped icosahedral positive-strand RNA viruses with 3'-polydenylated genomic RNAs which have the VPg covalently linked to their 5' ends. All members of the order have a similar mode of gene expression which involves the synthesis of large precursor polyproteins and their subsequent cleavage by a virus-encoded proteinase. The members of the order, all contain the similar gene order, membrane-bound protein-VPg-proteinase-polymerase, a feature shared with members of the filamentous family *Potyviridae*.

Use in Biotechnology

CPMV has been extensively used as a vector for the expression of foreign peptides and proteins in plants. The only other comovirus that has been deployed in biotechnology is BPMV. Several BPMV RNA2-based vectors have been developed which permit the insertion of foreign sequences for either protein expression or gene silencing in soybean. At present there are no reports of the use of a fabavirus in biotechnology.

Geographic Distribution

Individual comoviruses tend to have a somewhat restricted distribution. Clearly, the apparent distribution of a virus is governed, at least in part, by whether or not infection is diagnosed and reported. The following list, therefore, contains only those geographical areas where the presence of the virus has, to date, been confirmed. CPMV: Nigeria, Kenya, Tanzania, Japan, Surinam and Cuba; *Andean potato mottle virus* (APMV): Central and South America; BPMV: USA; *Bean rugose mosaic virus* (BRMV): Central America; BBSV: Europe and Africa; *Broad bean true mosaic virus* (BBTMV): Europe and North-west Africa; *Cowpea severe mosaic virus* (CPSMV): North, Central and South America; *Glycine mosaic virus*-GMV: Australia; *Pea mild mosaic virus* (PMiMV): New Zealand; *Quail pea mosaic virus* (QPMV): North and Central America; *Radish mosaic virus* (RaMV): USA, Japan and Europe; RCMV: Europe; *Squash mosaic virus* (SqMV): North Africa, Israel, China, Japan, Australia and North, Central and South America; *Ullucus virus C* (UCV): Peru and Bolivia.

Fabaviruses occur throughout the world and a wide variety of different isolates have been reported from different geographical regions have been reported.

Host Range

The host ranges of individual comoviruses tend to be rather narrow. Of the 15 members of the genus, ten (CPMV, BPMV, BRMV, BBSV, BBTMV, CPSMV, GMV, *Pea green mottle virus*-PGMV, PMiMV, QPMV and RCMV), in nature, infect predominantly, if not exclusively, legumes. The other four members of the group, APMV, RaMV, SqMV and UCV, infect predominantly members of the *Solanaceae*, *Cruciferae*, *Cucurbitaceae* and *Basellaceae* respectively.

By contrast, the experimental host range of Fabaviruses is wide: 328 species of 186 genera in 44 families have been listed as infectable by BBWV. *Lamium mild mosaic virus* (LMMV) has been less extensively tested but differs from BBWV in not infecting, for example, cowpea (*Vigna unguiculata*) or tomato (*Lycopersicon officinale* cv. Marmande).

Transmission

In nature, comoviruses are usually transmitted by leaf-feeding beetles, especially by members of the family Chrysomelidae. However, CPMV has been shown also to be transmitted by thrips and grasshoppers. The beetle vectors can acquire the virus by feeding for as little as one minute and can retain and transmit the virus for a period of days or weeks. Experimentally, all comoviruses are mechanically transmissible. In the case of BBSV, BBTV, CPMV, CPSMV and SqMV, transmission through seed has been reported.

Fabaviruses are transmitted by aphids in a non-persistent manner. The list of known vector aphids extends to some 20 species including *Acyrtosiphon pisum*, *Aphis craccivora*, *A. nasturtii* and *Macrosiphum euphorbiae*. However, there are unpredictable and unexplained differences between fabavirus isolates in the efficiencies of their transmission by different aphid species. There is only one report showing that BBWV is seed-transmitted. The transmission of fabaviruses by aphids is not known to require the presence in source plants of another 'helper' virus.

Epidemiology

The primary sources for infection of crop plants with comoviruses are transmission through seed and infection from wild hosts act as reservoirs of the viruses. It is also possible that virus which has overwintered in the beetle vector can act as a primary source of infection. Within-field spread is by the beetle vectors. Fabaviruses can be readily spread by their aphid vectors.

Symptomatology and Cytopathology

Generally, each virus has certain hosts in which the virus can spread systematically, causing mosaic or mottling symptoms, and other hosts in which the infection is confined to local lesions. Stunting of the host plant is sometimes observed, as is occasional systematic wilting and seed discoloration.

Infection of plant cells with comoviruses results in a number of characteristic cytopathological changes. These include the appearance of viral particles, either individually or as crystalline arrays, in the cytoplasm, a proliferation of cell membranes and vesicles in the cytoplasm, the appearance of amorphous inclusion bodies near or surrounding the nucleus and a variety of modifications to plasmodesmata.

Virions of all the fabaviruses occur in the cell cytoplasm of foliar mesophyll and epidermis. In some isolates, virions, virus-like shells and probably also capsid protein assemble into a variety of ordered arrays (tubules, rings, square patterns) that can be recognized by electron microscopy. Amorphous X bodies (spindle-shaped fibrous or crystalline inclusions visible using light microscopy) may have some diagnostic value.

Economic Importance

At present, BPMV, CPMV, CPSMV and RCMV are considered to be significant pathogens of legumes. Infection of soybeans with BPMV alone can cause yields to be reduced by 10%–17%. However, this figure can rise to 60% in plants doubly infected with BPMV and the potyvirus, Soybean mosaic virus. In Nigeria, infection of cowpeas with CPMV causes a great reduction in leaf area, flower production and yield. Infection of cowpeas with CPSMV has been shown to cause a 50% reduction in plant fresh weight and in the number and weight of pods. RCMV is of economic importance in forage production as it sometimes heavily infects clover. SqMV is a significant pathogen of cucurbits, problems associated with it being exacerbated by its high rate of seed transmission. Fabaviruses kill lettuce, bean and spinach plants and cause necrotic streaks in foliage of some pea cultivars. Symptoms in other crops are usually transient and have limited commercial significance – except in the People's Republic of China where complex intercropping patterns favor damaging epiphytotic also involving celery (*Apium graveolens*) and pakchoi (*Brassica chinensis*).

Glossary

Epidemic A wide spread of an infectious disease in the population at a specific time.

Host plant resistance The natural host plant species have the ability to control the parasite population. This is the most desired approach to control disease.

Koch's postulates The criteria first time developed in 1890 by Robert Koch that establishes the relationship between a disease and microbe. Following conditions must be fulfilled; the pathogen should be present in all symptomatic hosts, and after its isolation from the host it should be able to grow in pure culture, and when

reintroduced into a healthy host it must cause the disease. At the end, the pathogen must be isolated from this infected host.

Pathogen-derived resistance The type of resistance to specific pathogens that is created by engineering host to express genes or sequences derived from the pathogen, it interferes with the infection caused by this pathogen or its most related pathogen which has the same sequence.

Resistance breaking strain A strain of pathogen which breaks the resistance of host against a specific pathogen.

Introduction

Cotton leaf curl disease (CLCuD) is the most destructive disease of cotton (*Gossypium* spp. L.) and also for several other plants in the family *Malvaceae*. The disease is widespread in Africa (mainly Sudan, Egypt, Malawi, Nigeria and South Africa) and southern Asia where it is endemic across Pakistan and northwestern India. Recently, it is also been reported from southern China in non-cotton plants. Typical symptoms exhibited by CLCuD affected plants include vein thickening, upward or downward leaf curling, and on the main vein (underside the leaves) enations are formed that evolve into cup-shaped leaf-like structures (Fig. 1). CLCuD affected cotton plants are conspicuously greener than non-infected plants which is attributed to a higher density of chloroplasts in infected tissues. Symptoms of CLCuD vary between different varieties of cotton and also depend on the age of the infected plants. Plants infected at the early stage show severe symptoms like tightly rolled leaves, highly stunted growth and subsequently they produce no harvestable lint whereas plants which are infected at the late stage show just mild symptoms and their yield is not significantly reduced. CLCuD is caused by begomoviruses (genus *Begomovirus*, family *Geminiviridae*) in association with betasatellites (*Tolecusatellitidae*) and alphasatellites (*Alphasatellitidae*), all being transmitted by insect vector whiteflies (*Bemisia tabaci*). The disease complex is distinct between the two continents.

Since prehistoric times, cotton is being grown in almost all tropical and subtropical areas of the world and it is increasingly adapted to temperate climates. China, India, USA, Pakistan and Brazil are the major cotton producing countries in the world. The genus *Gossypium* consists of approximately 52 species, five of which are tetraploid, and all others are diploid. Only four species are cultivated which produce spinnable fiber for the textile industry. These include two allotetraploid species, *G. barbadense* (Pima/Egyptian cotton) and *G. hirsutum* and two diploid species, *G. arboreum* and *G. herbaceum*. *G. hirsutum* (also known as upland cotton) accounts for more than 90% of the cotton production in the world. Diploid cotton species are native to Asia and Africa and they were largely grown prior to *G. hirsutum* species that was introduced from the New world (NW). The Old world (OW) native species have natural resistance to CLCuD.

Fig. 1 Infected cotton (*Gossypium hirsutum*) plants showing typical symptoms of CLCuD. Symptoms include vein darkening, vein swelling, upward curling of the leaves and enations on the undersides of leaves (left). A severely infected plant showing a reduced leaf size, downward curling of leaf, leaf crumpling and severely stunted growth (right).

History of CLCuD

CLCuD in Africa

CLCuD was reported for the first time in 1912 from Nigeria, where it was sporadic and remained a minor problem. Its second outbreak occurred in the same country in 1924. Later in the year 1924, CLCuD was also reported from Sudan and in 1926 from Tanzania. In North-East Africa, (mostly Egypt and Sudan) species of cotton mostly cultivated is *G. barbadense*. CLCuD is endemic in these areas, although it is only sporadically a problem. An epidemic was reported in 1927–28 in Sudan which stimulated interest in this disease, and it was shown that whiteflies were responsible for its transmission. At that time extensive research established that the disease is also transmissible through graft and a virus-like agent was suspected as the causative agent although the actual causing agent was not identified. In those days the disease was controlled by imposing a period in which cotton was not grown and later they cultivated virus resistant *G. barbadense* varieties. CLCuD sporadically occurs in Africa but with no major economic losses.

CLCuD in Southern Asia

Prior to the 1980s, CLCuD was found sporadically in the Indian subcontinent. During the early-1990s, in Pakistan, the cotton production started to suffer heavy losses due to an epidemic of CLCuD. The disease was first reported near the city of Multan and soon it spread to almost all major cotton growing areas of Pakistan and also into the western part of India. Most probably this epidemic of CLCuD was attributed to the large-scale cultivation of two cotton varieties viz. CIM70 and S-12 which were high-yielding, but unfortunately highly susceptible to this local disease. *G. arboreum*, the native species of cotton is naturally immune to CLCuD, but this species does not produce cotton lint of high quality demanded by the processing industry. However, still farmers grow this species on a small scale. At the end of the 1990s, the cotton production reached again pre-epidemic levels, through the development and gradual adoption of tolerant and resistant cotton varieties. Unfortunately, this resistance did not last a long time, as it was broken in 2001, by the emergence of a resistance breaking combination of a virus strain of begomovirus and a betasatellite. This resulted in the 2nd epidemic of CLCuD in this region. Currently, there is no commercial cotton variety resistant to this disease complex. In 2015, begomoviruses associated with the first epidemic reappeared in cultivated cotton fields and the resistance breaking strain disappeared after 2015.

Etiology of CLCuD

In both CLCuD affected regions [Africa (Sudan and Egypt) and Indian subcontinent] the etiology of the disease has been determined. In both regions, it was found that the disease is caused by monopartite begomoviruses (genus *Begomovirus*, family; *Geminiviridae*) associated with single-stranded DNA satellite molecules viz., betasatellites (*Tolecusatellitidae*) and alphasatellites (*Alphasatellitidae*). Betasatellites encode a single protein β C1 which is a pathogenicity determinant, whereas alphasatellites play no apparent role in the etiology of CLCuD. However, it has been found in all cases of CLCuD in the field.

Elucidation of the Etiology of CLCuD

In Africa, since 2002 CLCuD is caused by a single species of begomovirus viz. *Cotton leaf curl Gezira virus* (CLCGeZV) in association with *Cotton leaf curl Gezira betasatellite* (CLCGeZB) and *Cotton leaf curl Gezira alphasatellite* (CLCGeZA). Although this disease complex remained permanently associated with CLCuD in Africa, recently and for the first time, in west and central Africa, a bipartite begomovirus, *Cotton yellow mosaic virus* (CYMV) was also reported in a non-cultivated cotton species i.e. *Gossypium raimondii*.

CLCuD caused huge losses to cotton industries in both Pakistan and India in the early 1990s. This initiated a deep investigation into the etiology of the CLCuD. Initially, several species of begomoviruses were isolated and sequenced from cotton in both countries but their infectivity was not tested in cotton. So, the Koch's postulate was not fulfilled at that time. Later, efforts were made to introduce one of these begomoviruses i.e., CLCMuIV into cotton which showed atypical and mild symptoms. These results indicated that either another component was required for the disease or CLCMuIV was not responsible for the CLCuD.

Begomoviruses are typically divided into two groups i.e., monopartite and bipartite based on their genomic components. The bipartite begomovirus has two component DNA-A and DNA-B approximately equal size (2.7 kb) whereas monopartite begomoviruses have single genomic components equivalent to DNA-A of bipartite begomoviruses. Old world monopartite begomoviruses are often also associated with DNA satellites referred to as betasatellites and alphasatellites.

During the first epidemic, it was troubling that CLCMuIV alone was unable to infect cotton to develop the typical symptoms of CLCuD and the same situation was noticed with several other begomoviruses. When CLCuD-affected plants were further analyzed then a novel additional, subviral component was identified. Similar components had been identified in association with several monopartite begomoviruses. These components had been named as DNA-1 (now known as alphasatellite). However, in the case of CLCuD, it was found that alphasatellites did not play an essential role in the disease. Nevertheless, this finding promoted the reinvestigation of subviral DNA molecules, which might be associated with monopartite begomoviruses. In the mean-time, with a different study done with the monopartite *Ageratum yellow vein virus* (AYVV), another sub-genomic DNA component, named DNA- β (betasatellite), was identified. Shortly after this discovery a similar component DNA- β was also identified associated with CLCMuIV. Inoculation of CLCMuIV with the associated betasatellite induced all typical symptoms of CLCuD in cotton, hereby establishing the etiology of the disease and Koch's postulate was fulfilled. Betasatellites encode a single protein referred to as β CI on its complementary strand which acts as a pathogenicity determinant.

Components of the CLCuD Complex

Begomoviruses Associated With CLCuD

CLCuD in Africa

A single OW monopartite begomovirus viz. *Cotton leaf curl Gezira virus* (CLCGeZV), has been found in association with CLCuD in Africa. However, recently *Cotton yellow mosaic virus* (CYMV); a bipartite OW begomovirus has been isolated from non-cultivated cotton (*Gossypium raimondii*) for the first time in west and central Africa. CLCGeZV is more closely related to begomoviruses originating from the African Mediterranean region infecting malvaceous plants, and distantly related to begomoviruses associated with the Asian CLCuD. Begomoviruses are geographically related, supporting the distinct evolutionary origin of begomoviruses causing CLCuD in Asia and Africa. In 2005, CLCGeZV-EG (Egyptian strain) was isolated from cotton in Sindh, Pakistan, in a mixed infection, but its cognate betasatellite viz., CLCGeZB was not found, instead it was trans-replicating two asian betasatellites; CLCMuLB and Chili leaf curl betasatellite (ChLCB). Interestingly, until now, CLCGeZV has not been reported from Punjab in Pakistan and from India.

CLCuD in the Indian subcontinent

The first epidemic of CLCuD in the Indian subcontinent was associated with several distinct begomovirus species which are CLCMuIV, *Cotton leaf curl Alabad virus* (CLCAIaV), *Cotton leaf curl Kokhran virus* (CLCKokV), *Tomato leaf curl Bangalore virus* (ToLCBanV) and *Papaya leaf curl virus* (PaLCV). They were associated with the disease either in single or multiple co-infections (Fig. 2). Some of these viruses induced CLCuD in cotton plants when they were co-inoculated with CLCMuLB whereas, only ToLCBanV was able to cause tomato leaf curl disease in the absence of a betasatellite. However recently, it was shown to trans-replicate multiple betasatellites which resulted in the increased pathogenicity in tomato and a model plant. CLCBanV was reported from *G. barbadense* in southern India but it was not affecting the north of India where CLCuD was epidemic. In addition, experiments to demonstrate that it could infect cotton and cause CLCuD were not successful.

In the late 1990s scientists had developed some cotton resistant varieties which helped to restore the production to pre-epidemic levels. But, unfortunately in the year 2001, a resistance breaking begomovirus appeared. It was a recombinant of CLCMuIV and CLCKokV and referred to as CLCKokV-Burewala strain (CLCKokV-Bur). It was first identified from Punjab in Pakistan then also spread to north-western India and it became the second epidemic of CLCuD in the region. This strain had a truncated TrAP (AC2) protein which was speculated to cause the resistance breaking. However, since that time, the existence of CLCKokV-Bur with an intact C2 gene has been shown. Therefore, the reason for this strain to break the resistance and cause the second epidemic has not been elucidated.

In 2014, two bipartite begomoviruses have also been identified from cultivated cotton plants in Pakistan. The most important one is *Tomato leaf curl New Delhi virus* (ToLCNDV), which was frequently identified from cotton in both Sindh and Punjab provinces of Pakistan, whereas the other was *Tomato leaf curl virus* (ToLCV) reported from the same country. Moreover, the identification of *Chickpea chlorotic dwarf virus* (CpCDV), a *Mastrevirus* (*Geminiviridae*), and *Okra enation leaf curl virus* (OELCV), a typical begomovirus from infected cotton, has further complicated the situation. It has been shown experimentally that ToLCNDV enhances the accumulation of CLCMuB-Bur by synergistically interacting with CLCKokV-Bur in the infected plants. Moreover,

CLCMulB has been shown to be trans-replicated by the DNA-A component of ToLCNDV, in the absence of its DNA-B component, and causing typical symptoms of CLCuD in cotton. Interestingly, in 2015, multiple begomoviruses which were associated with the first epidemic of CLCuD in 1990s were found in cultivated cotton in Vehari, Punjab, in Pakistan and in the same year CLCMulV was exclusively identified from Punjab, in India. In both studies CLCKokV-Bur was not identified in cultivated cotton.

Identification of multiple begomoviruses with a single species of betasatellite in cotton while causing a single disease, suggests that these begomoviruses, also identified from many alternative hosts, most probably moved to cotton, where they could interact with CLCMulB to cause a unique cotton disease. Moreover, recently it was reported that non-cultivated cotton species from Multan, Punjab, in Pakistan (the region considered as hotspot for begomoviruses and satellites associated with CLCuD) were continuously infected by multiple begomoviruses, associated with multiple DNA satellites but with the unique identical betasatellite, CLCMulB. These plants are therefore reservoirs for a collection of begomoviruses and satellites. The presence of multiple begomoviruses makes it easy to overcome resistance against individual viruses and facilitates adaptation to other hosts. In addition, in the Indian subcontinent there are many other monopartite begomoviruses that are not found in cotton, possibly suggesting that these few species of begomoviruses recently adapted to cotton. Moreover, some begomoviruses that are not reported in the region, such as ToLCV, originating from Australia, and *Ageratum yellow vein virus* originating from southeast Asia, as well as Tomato yellow leaf curl virus (TYLCV), were shown capable experimentally to trans-replicate the CLCMulB (the unique betasatellite associated with CLCuD). The capability of CLCMulB to interact with a multitude of begomoviruses provides a huge flexibility for the cotton disease to occur and makes it a real threat to cotton production worldwide.

It has been shown experimentally that CLCMulV is efficiently transmitted by the whitefly species Asia II 1 as compared to Middle East Asia minor 1 (MEAM1), and Asia II 1 is the dominant species in major cotton growing areas of Pakistan and India. Moreover, the Asia II 1 whitefly genome has been sequenced, and compared to that of MEAM1, revealing variations in genes involved in insecticide resistance and virus transmission. These findings may explain the rapid spread of CLCuD but also its current limitation to the Indian subcontinent. If Asia II 1 was to become dominant in other parts of the world, most probably it may allow the rapid transfer of CLCuD associated begomoviruses and satellites to become a serious global threat. In addition, the Faisalabad strain of CLCMulV was recently isolated from *Hibiscus rosasinensis* and from okra in the southern China, but it did not become epidemic in China, most probably due to the local whitefly species.

With all this information, a third epidemic of CLCuD could be expected to occur soon, possibly with distinct begomoviruses, but with the same associated DNA satellite components (Fig. 3). A recent Pakistan report survey about whiteflies and begomoviruses from all major cotton growing areas (both Sindh and Punjab in Pakistan), indicates that the dominant whiteflies are of the species Asia II 1 and they all carry CLCMulV-Raj, a new strain of CLCMulV. The most recent isolates of CLCMulV from India and Pakistan indicate a novel clade in the phylogenetic tree of begomoviruses associated with CLCuD and this may be associated with a potential third epidemic of CLCuD. Similarly, the most recent strain of betasatellite viz., CLCMulB^{Veh} has been identified from whiteflies as well as cotton, so it may also be associated with a possible third epidemic of the disease.

CLCuD-Associated Alphasatellite Components

Alphasatellites (*Alphasatellitidae*) are the satellite components associated with disease complexes of monopartite begomovirus (Fig. 3). They are circular, single-stranded (ss)DNA molecules have about half the size (~1380 nt) of their helper viruses. With a single gene on virion-sense orientation which encodes a protein required for their replication (rolling-circle replication) initiation. The product of this gene is called replication associated protein (Rep) of the plant-infecting ssDNA viruses. In the cells of host plants, alphasatellites are capable of autonomous replication so for their replication they do not depend on their helper viruses. However, for movement within plants and transmission between plants, these molecules require the helper geminiviruses. Presumably, they are trans-encapsidated in the coat protein of the helper geminiviruses. Although alphasatellites are not apparently required to induce the disease symptoms in host plants it was however recently reported that Rep of alphasatellites may have a role in gene silencing mechanism in plants.

Fig. 2 Neighbor-joining phylogenetic tree of begomoviruses was reconstructed using bootstrap method with 1000 replicates (percentage bootstrap value is shown on the right corner of each branch when >50%). The size of the triangles is roughly proportionate to the number of isolates in the cluster. The color code is for identifying viruses originally described on cotton in the Indian subcontinent (yellow), or for newly identified viruses on cotton but from other origin in the Indian subcontinent (green), light brown is for African viruses, light blue is for ACMV identified in Pakistan but originally described in Africa, pink is from cotton viruses from America and orange is for a mastrevirus identified in cotton in Pakistan. The triangles with a double line are those for the bipartite viruses versus 1 line for the monopartite viruses. *Abbreviations used for different species and strains are as follows:* CChSV (Cotton chlorotic spot virus), ChiLCV (Chili leaf curl virus), CLCAIaV-Ala (Cotton leaf curl Alabad virus-Alabad), CLCAIaV-Har (Cotton leaf curl Alabad virus-Haryana), CLCAIaV-Kar (Cotton leaf curl Alabad virus-Karnal), CLCAIaV-Lob (Cotton leaf curl Alabad virus-Lobatum), CLCAIaV-Mul (Cotton leaf curl Alabad virus-Multan), CLCBaV (Cotton leaf curl Bangalore virus), CLCBarV (Cotton leaf curl Barasat virus), CLCGeV (Cotton leaf curl Gezira virus), CLCKokV-Bur (Cotton leaf curl Kokhran virus-Burewala), CLCKokV-Kok (Cotton leaf curl Kokhran virus-Kokhran), CLCKokV-Sha (Cotton leaf curl Kokhran virus-Shadadpur), CLCMirV (Cotton leaf curl Mirzapur virus), CLCMulV-Dar (Cotton leaf curl Multan virus-Darvinii), CLCMulV-Fai (Cotton leaf curl Multan virus-Faisalabad), CLCMulV-His (Cotton leaf curl Multan virus-Hisar), CLCMulV-PK (Cotton leaf curl Multan virus-Pakistan), CLCMulV-Raj (Cotton leaf curl Multan virus-Rajasthan), CLCrV (Cotton leaf crumple virus), CpCDV (Chickpea chlorotic dwarf virus), CYMV-DNA-A (Cotton yellow mosaic virus-DNA-A genome), OELCV (Okra enation leaf curl virus), PaLCV (Papaya leaf curl virus), SLCV (Squash leaf curl virus), ToLCBaV (Tomato leaf curl Bangalore virus), ToLCGujV-DNA-A (Tomato leaf curl Gujarat virus-DNA-A genome), ToLCNDV-DNA-A (Tomato leaf curl New Delhi virus-DNA-A genome).

Fig. 3 Genomic organization of begomoviruses and associated alphasatellites and betasatellites. A; genome organization of a monopartite begomovirus and associated satellites in the first epidemic of CLCuD in Asia, B; genome organization of a monopartite begomovirus and associated satellites found in the second epidemic of CLCuD in Asia, C; genome organization of a monopartite begomovirus and associated satellites expected in a third epidemic (left), and genome organization of a bipartite begomovirus expected in a third epidemic (right), D; genome organization of a monopartite begomovirus and associated satellites found in Africa and E; genome organization of a bipartite begomovirus found in Africa. *Abbreviations*: CR; conserved region, Rep; Replication-associated protein, TrAP; Transcription associated protein, Ren; Replication Enhancer protein, CP; Coat Protein, MP; Movement protein, NSP; Nuclear Shuttle protein, β C1; Beta C1; SCR; Satellite Conserved Region. A-rich; Adenine rich region.

Surprisingly, the alphasatellite are more closely related to nanovirus genomic components that also encode a Rep protein. Nanoviruses (family *Nanoviridae*) are a group of plant-infecting, ssDNA viruses that are transmitted by aphids. Similarly, the master Rep (mRep) component which encodes the Rep required for replication of all nanovirid components. These satellite-like molecules and mRep components are however quite distinct from each other based on their genomic sequence and genome organization. The position of the promoter of these components is different from that of the mRep. It is believed that alphasatellites associated with begomoviruses have evolved directly from the satellite-like components of nanoviruses.

The major difference between alphasatellites and satellite-like components of nanovirus is their genomic size. The average size of alphasatellites is ~1380 bp, which is almost half the size of helper begomoviruses, whereas the genome of nanovirid components is typically of 1000–1100 bp. Most of this increased size is occupied by an adenine (A) rich region of about 200 bp. The function of this A-rich region it still not clear; it was observed that alphasatellites with deleted A-rich region were capable to replicate and move in plants in the presence of a helper begomovirus. There is an understated selection mechanism to maintain

the size of alphasatellites, most probably due to efficient encapsidation by the coat protein of their helper virus. Since the first identification of Cotton leaf curl Multan alphasatellite (CLCMulA) associated with the cotton begomovirus, multiple alphasatellites have been reported from CLCuD infected cotton in the Indian subcontinent. They include *Cotton leaf curl Multan alphasatellite* (CLCMulA), *Gossypium darwinii* symptomless alphasatellite (GDarSLA), *Ageratum conyzoides* symptomless alphasatellite (AConSLA), *Cotton leaf curl Burewala alphasatellite* (CLCBurA), *Okra enation leaf curl alphasatellite* (OELCA), *Ageratum yellow vein India alphasatellite* (AYVINA) and *Tomato leaf curl alphasatellite* (ToLCA). Interestingly, in North-East Africa, the only alphasatellite component reported with the CLCuD complex is *Cotton leaf curl Gezira alphasatellite* (CLCGezA).

CLCuD-Associated Betasatellite

Betasatellites are ssDNA satellites (genus *Betasatellite*, family *Tolecusatellitidae*) which are associated with many monopartite begomoviruses. Presumably, betasatellites are trans-encapsidated by the coat protein of helper viruses to allow movement in plants, as well as transmission by whiteflies. Betasatellites also depend on the helper geminivirus for their replication. In infectivity assays betasatellites were found responsible for the high titer of the helper virus, to levels found in their original host in the field. This showed that betasatellites are involved in either the replication of their helper virus, their systemic movement in the host, and/or suppressing the gene silencing host defense mechanism against viruses. The size of the betasatellites is about half (1350 bp) of the size of their helper begomovirus. Interestingly, they share no sequence homology with their helper virus except the stem-loop structure which contains the conserved nonanucleotide (TAATATTAC). This stem-loop structure is present in a satellite conserved region (SCR) which is about 100 nt and highly conserved among betasatellites. Betasatellites encode a single gene, the product of which is known as β C1 protein (~118 aa) which has a critical role in pathogenicity and symptoms determination as it alters several cellular processes of the host like ubiquitination, autophagy and suppression of gene silencing (post-transcriptional gene silencing (PTGS) or transcriptional gene silencing (TGS)). After the first discovery of the *Ageratum yellow vein betasatellite* (AYVB), they have been found from a diverse range of hosts. More than 1800 complete betasatellite genomes were sequenced and their comparison shows that they are highly diverse. Surprisingly, only a single species of betasatellite, *Cotton leaf curl Multan betasatellite* (CLCMulB) is associated with CLCuD. Both experimentally and in the field, this species was found to be trans-replicated by several distinct begomoviruses. When β C1 of CLCMulB is expressed in tobacco plants, either stably transformed or transient expression, it induces virus-like symptoms, which demonstrates that in the CLCuD complex, the β C1 is the most important pathogenicity and symptom determinant.

The second epidemic of CLCuD, which was caused by a recombinant begomovirus (from two different species), was also associated with a recombinant CLCMulB, in which CLCMulB^{Mul} (Multan strain) recombined with Tomato leaf curl betasatellite (ToLCB). In Sindh province of Pakistan, another novel strain of CLCMulB viz. CLCMulB^{Sha} (Shadadpur strain) was also found to be associated with CLCuD whereas in Punjab only CLCMulB^{Bur} was found. Most recently, a novel strain CLCMulB^{Veh} (Vehari strain) was identified from Vehari, Punjab, in Pakistan and from India. Identification of different strains of CLCMulB indicates the co-evolution of CLCMulB with helper begomoviruses. In Africa, Cotton leaf curl Gezira betasatellite (CLCGezB) is the only betasatellite found so far in association with CLCuD in Sudan and it is quite distinct from CLCMulB in the Indian subcontinent.

Control of CLCuD

Strategies to Control the CLCuD Complex

The CLCuD is a serious threat to cotton cultivation in the countries where whiteflies are a major pest. There are mainly two types of strategies i.e. a short term strategy, involving management practices and a long term strategy involving the development of resistant cotton varieties either by conventional or non-conventional methods.

Short Term Strategies

After the spread of CLCuD on a massive scale during the first epidemic, many short-term strategies were adopted to minimize the losses by reducing the whitefly population in the field. For instance, treatment of seeds to avoid early establishment of vector populations, spraying insecticide on cotton crop to control whitefly populations, eradication of weeds (alternative hosts of viruses), providing balanced dose of fertilizers and biological agents....

Application of selective insecticide is most important in controlling the whitefly population. Recently, the whole genome sequence of Asia II 1 showed genetic variance in insecticide resistance related genes as compared to MEAM1. Most probably, this may be the impact of misuse of insecticides to control whitefly population. Moreover, it is advisable to spray insecticide on cotton crop 70–90 DAS (days after sowing) to control the whitefly population as seed treatment protects from whitefly infestation up to 75 DAS in some reports. After this period, cotton plants are grown enough that they can escape the disease, and losses are reduced.

As CLCuD associated viruses are not seed-borne they depend upon the alternative hosts to survive the off season. Alternative hosts are many other plants like okra, tomato, tobacco, *ageratum*, *hibiscus* and many weeds. Avoiding the cultivation of alternative host in off season and proper eradications of weeds may reduce the disease incidence.

Further damage due to this disease can be reduced by applying a balanced dose of nutrients especially using potassium to boost the resistance against the disease whereas excessive use of nitrogen reduces the resistance. So, it is advised to use the balanced ratio of potassium and nitrogen which helps to reduce the disease severity.

Long Term Strategies

Genetics of host plant resistance to CLCuD

For durable resistance strategy to control the disease, it is most important to breed virus resistant varieties with enough genetic diversity. Before developing disease resistant varieties of cotton, the key components is designing a breeding plan for the genetic basis of disease resistance and its inheritance. Unfortunately, very little is known about the molecular basis of the disease resistance in cotton. *G. arboreum*, native species of Asia is naturally immune to the Asian CLCuD complex, but it is grown on a small scale because it produces a poor quality fiber. The transcriptomics study of *G. arboreum* under virus stress revealed multiple resistance mechanisms against CLCuD. The exotic species *G. hirsutum* produces good quality and quantity of fiber and is commercially cultivated on large scale. Unfortunately, this species showed limited resistance/tolerance to CLCuD and only two varieties, LRA5166 and CP15/2, have been used to develop resistance in the late 1990s. Losses due to CLCuD were successfully alleviated by cultivating these varieties and cotton production was regained to the level prior to the epidemic. Unfortunately, this resistance was broken by the evolution of novel strain of begomovirus viz., CLCKokV-Bur. Currently, all commercial varieties are highly susceptible to CLCuD. Recently, transcriptomic studies in *G. hirsutum* under whitefly transmitted virus stress provided some insights into disease susceptibility in cotton and predicted some important genes to be involved in the compatible interaction of CLCuD associated disease complex and cotton. These findings will have to be validated to pinpoint the genes that make *G. hirsutum* susceptible and *G. arboreum* resistant. Although some efforts were made in introgression virus resistance from *G. arboreum* into *G. hirsutum*, they were not successful in developing a resistant variety suitable for agriculture. It was also tried to transfer the desired traits from *G. hirsutum* to *G. arboreum* (after doubling its chromosomes) but unfortunately, it also remained unsuccessful in the development of commercial varieties. Finally, about 5000 accessions of *G. hirsutum* from USA and some introgression lines were screened in Pakistan against CLCuD. This work identified the “Mac-07” accession, and 95 other accessions, that remained asymptomatic under field conditions, hoping that a good source of resistance could be used in the near future.

Engineered Resistance to the CLCuD Complex

Because of the difficulty to identify and transfer useful genes of resistance to CLCuD from *G. hirsutum* germplasm, multiples strategies have been deployed using genetic engineering approach to develop cotton plants resistant to this viral disease and its insect vector whitefly. Generally, these strategies are of two types; firstly the “pathogen derived resistance” in which full length viral genes or different small conserved portion of the virus genome are used and secondly the ‘non-pathogen derived resistance’ in which genes from distantly related genetic source are used.

Pathogen Derived Resistance (PDR)

Introducing the genomic part (gene or its part) of virus that is conserved among different viruses into the host plant is the most desirable strategy for broad spectrum resistance to control disease. Following strategies have been adopted for the development of resistance in which genomic information of pathogen is used.

Antisense RNA technology

In this technology antisense RNA molecule suppresses the complementary target mRNA. When antisense RNA against Rep gene of the virus was introduced in cotton, it suppressed the replication of the virus, similarly in another study when the coat protein gene (AV1) was targeted by antisense RNA in transgenic cotton, it arrested the movement, replication and encapsidation of the target virus. Transgenic cotton was also developed using antisense AV2 (350vbp) gene and transgenic plants were resistant to CLCuD. Similarly, two truncated forms of the Rep gene were introduced in *G. hirsutum*, which inhibited the replication of both viral and satellite genomes. Recently antisense β C1 gene was also introduced in cotton and transgenic plants were symptomless under virus stress. However, none of these transgenic cotton lines were successful under field conditions.

RNAi technology

The principle of the RNAi technology utilizes the transcriptional gene silencing (TGS) and post-transcriptional gene silencing (PTGS) and has been deployed to develop resistance against different viruses, such as the African cassava mosaic virus (ACMV), the Mung bean yellow mosaic virus (MYMV) and many others. A 21 nt of V2 of CLCKokV-Bur strain was used to develop the artificial microRNA (amiRNA) and construct was transformed in *Nicotiana benthamiana* plants and transgenic plants showed resistance to CLCKokV-Bur. Recently, RNAi based construct against the V2 gene of CLCKokV-BuR was transformed in two cotton species viz. MNH-786 and VH-289 and transgenic cotton plants, when challenged to whitefly under control conditions, showed a low titer of

the virus for transgenic plants as compared to non-transgenic. It was concluded that these transgenic plants could be used in the fields to control the CLCuD but have so far not proven successful in the field.

Non-Pathogen Derived Resistance

In this strategy, genes from host or non-host are used to develop the resistance against the disease. For instance, genes which confer DNA binding proteins, antiviral antibodies, coat binding proteins etc. have been introduced in plants to develop resistance to CLCuD. Recently, Tma12 a protein identified from fern to confer resistance to whitefly, was transformed in cotton, and one of the transgenic lines showed increased resistance (> 99%) to whitefly. Moreover, this protein was non-toxic in rats which shows that this is safe to use in other crops.

Genome Editing Strategy: CRISPR/Cas9 Approach to Control CLCuD

CRISPR/Cas9 system has been exploited in many organisms for genome editing by transforming the Cas9 protein. One of the desirable properties of this system is that it can targets multiple sites, which can be utilized to control multiple viruses in plants. Resistance to different geminiviruses has already been achieved through this system. For example, genome of *Bean yellow dwarf virus* (BeYDV) was cut down when CRISPR–Cas9 system was applied in bean against this virus and resulted in reduced disease symptoms. Similarly, this system was used against TYLCV and *Beet curly top virus* (BCTV) and resulted in the reduced disease symptoms. In cotton this system is in progress to target CLCKokV-Bur and associated betasatellite genes and conserved regions. However, its success is yet to be demonstrated. Recently, it was reported that expressing Cas9 in cassava was unable to protect it from geminiviruses infections where viruses multiply faster than edited by Cas9 and this also helps in rapid evolution of viruses. This makes an alarming sign for future results of CRISPR/Cas9 use in cotton against CLCuD associated disease complex (as multiple sgRNAs are being used). In this scenario it is most important to explore the actual molecular mechanisms involved in compatible interactions of virus-host vector and identify some susceptible genes in cotton which can be knocked out by CRISPR/Cas9 system, or resistance genes for introgression in susceptible commercial varieties.

Glossary

Affimers Small proteins that mimic antibodies.

Nanobiotechnology Refers to the intersection of nanotechnology and biology. Given that the subject is one that has only emerged very recently, bionanotechnology and nanobiotechnology serve as blanket terms for various related technologies.

Nanotechnology Also known as “nanotech” is manipulation of matter on an atomic, molecular, and supramolecular scale.

Viral protein genome-linked A protein covalently attached to the 5′ end of positive strand viral RNA and acting as a primer during RNA synthesis.

Virus replication complexes Intracellular complexes formed by association with intracellular membranes that are sites for stages in the replication cycle of a virus.

β-barrel Beta-sheet composed of tandem repeats forming a closed structure.

Introduction

Since its first isolation in 1959, Cowpea mosaic virus (CPMV) has served as a model icosahedral plant virus due to the high yield, ease of isolation and stability of its particles. As a consequence, it has been at the forefront of both genetic and structural studies of plant viruses and has been widely deployed in bionanotechnology. Thus, CPMV can be considered alongside viruses such as Tobacco mosaic virus (TMV) and Brome mosaic virus (BMV) as one of the “classic” plant viruses.

Taxonomy and Classification

CPMV is the type species of the genus *Comovirus* (which includes 14 additional members). The genus *Comovirus* is classified, together with the genera *Fabavirus* and *Nepovirus*, within the sub-family *Comovirinae* of the family *Secoviridae*. Within the subfamily the greatest affinity is between the genera *Comovirus* and *Fabavirus*, both of which are insect-, as opposed to nematode-, transmitted. On a wider scale, consideration of genome structure and organisation, translational strategy and aa homologies between the virus-encoded proteins has led to the family *Secoviridae* being one of the 6 families within the order *Picornavirales*. Historically, the family *Secoviridae* had been grouped within the same “superfamily” as the family *Potyviridae* but the two families are now separately classified.

Biology

CPMV was first isolated from infected cowpeas (*Vigna unguiculata*) in Nigeria in 1959. Subsequently it has been found to occur in Nigeria, Kenya, Tanzania, Japan, Surinam and Cuba. It causes typical mosaic symptoms on infected plants (Fig. 1). While its natural host is cowpea, it can infect other legumes and *Nicotiana benthamiana* has proven to be an extremely valuable experimental host. In nature, transmission is usually by leaf-feeding beetles, especially by members of the Chrysomelidae. However, CPMV has been shown also to be transmitted by thrips and grasshoppers. The beetle vectors can acquire the virus by feeding for as little as one minute and can retain and transmit the virus for a period of days or weeks. The virus does not, however, multiply in the insect vector. Experimentally, CPMV is mechanically transmissible.

In Nigeria, infection of cowpeas with CPMV causes a great reduction in leaf area, flower production and yield. Infected plant cells show a number of characteristic cytological changes. These include the appearance of viral particles, a proliferation of cell membranes and vesicles in the cytoplasm, and a variety of modifications to plasmodesmata.

Fig. 1 CPMV symptoms and particles (A) Mosaic symptoms on the trifoliate leaves of a CPMV-infected *Vigna unguiculata* plant (right) compared to an uninfected plant (left). (B) Transmission electron micrographs of purified particles of CPMV at two different magnifications. The particles were negatively stained with 2% (w/v) uranyl acetate.

Physical Properties of Viral Particles

CPMV particles are icosahedral, non-enveloped with an average diameter of 28 nm (Fig. 1). Up to 2 g of particles can be obtained per kg of fresh infected cowpea tissue and they can be readily purified by polyethylene glycol precipitation and differential centrifugation. The particles are very stable with a thermal inactivation point in plant sap of 65–75°C and a longevity in sap of 3–5 days at room temperature. Once purified, the particles can be stored for prolonged periods at 4°C. The ease with which virus particles can be propagated, purified and stored has undoubtedly contributed to the early popularity of CPMV as an object of study.

Preparations of CPMV particles can be separated into three components on density gradients that are designated top (T), middle (M) and bottom (B), with sedimentation coefficients of 58S, 95S and 115S, respectively. The three components have identical protein compositions, containing 60 copies each of a large (L) and small (S) coat protein (CP), with sizes 42 kDa and 24 kDa, respectively, as calculated from the nucleotide sequence. The discovery, in 1971, that CPMV particles contained equimolar amounts of two different polypeptides suggested that the capsids had an architecture more similar to the animal picornaviruses than to other plant viruses which has been previously examined. This provided an early clue as to the common origins of plant and animal viruses.

The difference in the sedimentation behaviour of the three centrifugal components of CPMV lies in their RNA contents. Top components are devoid of RNA, while middle and bottom components each contain single molecules of positive-strand RNA of 3.5 and 6.0 kb respectively. The two RNA molecules were originally termed middle (M) and bottom (B) component RNA after the component from which they were isolated. However, more recently they have been referred to as RNA2 and RNA1, respectively. The three-component nature of CPMV preparations is summarized in Fig. 2. The determination of the component structure of the virus, and particularly the relationship between this and infectivity, was an important step in establishing the principle that plant viruses frequently have divided genomes, the individual components of which are separately encapsidated.

CPMV preparations are not only centrifugally heterogeneous but can also be separated in two forms, fast and slow, electrophoretically. Both electrophoretic forms contain all three centrifugal components. The proportion of the two electrophoretic forms in a given virus preparation varies both with the time after infection at which the virus was isolated and the age of the preparation itself. Conversion of one form to the other is caused by loss, through proteolysis, of 24 aa from the C terminus of the S protein.

Viral Structure

X-ray crystallographic and cryo-electron microscopy (cryo-EM) studies on CPMV, using either a natural mixture or individual components, have provided a detailed picture of the arrangement of the two viral CPs in the three-dimensional structure of the particle. Overall, the virions have icosahedral symmetry, with 12 axes of fivefold and 20 axes of threefold symmetry and resemble a classic $T=3$ particle. However, since there are two different types of CP subunit (L and S), their arrangement is usually referred to as pseudo $T=3$ or $P=3$. The two CPs taken together consist of three distinct β -barrel domains, two being derived from the L and one from the S protein. Thus, in common with the $T=3$ viruses, each CPMV particle is made up of 180 β -barrel structures. The S protein, with its single domain, is found at the fivefold symmetry axes and therefore occupies a position analogous to that of the A type subunits in $T=3$ particles. The N- and C-terminal domains of the L protein occur at the threefold axes and occupy the positions equivalent to those of the C and B type subunits of a $T=3$ particle respectively (Fig. 2). This detailed analysis confirmed the earlier suggestion that CPMV particles are structurally homologous to those of picornaviruses, with the N- and C-terminal domains of the L protein being equivalent to viral protein VP2 and viral protein VP3, respectively, and the S protein being equivalent to viral protein VP1; there is no equivalent of VP4. While no RNA could be seen in the crystallographic structures of either the M or B components of CPMV, cryo-EM analysis revealed that the encapsidated RNA forms concentric shells, with the strongest density being found directly beneath the twofold symmetry axes of the capsid. In common with other members of the order *Picornavirales*, the specific incorporation of the genomic RNAs into particles appears to be based on their ability to be replicated.

Fig. 2 Molecular structure of CPMV (a) Organisation of the two single-stranded RNA molecules that comprise the genome. Both RNAs have a VPg (red circle) linked to their 5' ends and both are polyadenylated. Excluding the poly(A) tail, RNA1 is 5889 nt in length and contains a single ORF that is processed by the 24K protease (Pro) to give the viral proteins required for RNA replication. RNA2 is 3481 nt in length and encodes the structural CPs, Large (L) and Small (S), as well as the protein required for the movement of CPMV virions from cell-to-cell. (b) Gradient separation of a natural mixture permits separation into three components. Empty CPMV particles sediment at the top (CPMV-T), RNA2-containing particles sediment in the middle (CPMV-M) and RNA1-containing particles sediment at the bottom of the gradient (CPMV-B). (c) An asymmetric unit of synthetic CPMV empty virus-like particles (eVLP) as revealed by cryo-electron microscopy. Both domains of the CP-L subunit are shown in green, while single domain of the CP-S is shown in blue. The C-terminal extension of the CP-S, visible in eVLPs, but not in particles from infectious virus particles, is coloured pink. (d) The icosahedral organisation of CPMV. Each of the 60 asymmetric units comprises one copy of the L subunit and the S subunit (coloured as in c). A view down the two-fold axis is shown. Reproduced from Hesketh, E.L., Meshcheriakova, Y., Dent, K.C., *et al.* 2015. Mechanisms of assembly and genome packaging in an RNA virus revealed by high-resolution cryo-EM. *Nature Communications* 6, 10113.

As well as the natural components, the structure of synthetic empty virus-like particles (eVLPs), that lack any detectable RNA, has been determined by both crystallography and cryo-EM. These particles were shown to be essentially identical to the natural components; however, it was possible to visualize some of the 24 aa that are normally cleaved from the C-terminus of the S protein. These structural studies, together with mutagenesis of the 24 aa segment, has enabled a model for the assembly of CPMV particles to be generated in which the 24 aa promote pentamer formation followed by the formation of RNA binding sites at the two-fold symmetry axes (Fig. 3). The presence of the C-terminal portion of the 24 aa segment on the particle surface is also important in permitting efficient systemic movement of the virus.

Genome Structure

Both M and B (but not T) components of a virus preparation are essential for infection of whole plants. As CPMV is a positive-strand RNA virus, a mixture of the genomic RNAs within the particles can also be used to initiate an infection. However, RNA1 is capable of independent replication in individual plant cells but this leads to the establishment of gene silencing, rather than a productive infection, in the absence of RNA2. Both genomic RNAs have a small basic protein (VPg) covalently linked to their 5' termini and both are polyadenylated at their 3' ends. The elucidation of the overall structure of the RNA segments once more underscored the similarity between CPMV and picornaviruses. However, unlike picornaviruses, the VPg is linked to the viral RNA via the β -hydroxyl group of its N-terminal serine residue rather than via a tyrosine. The VPg is not required for the viral RNAs to be infectious.

The complete nucleotide sequences of both genomic RNAs were reported in 1983, making CPMV one of the first RNA plant viruses to be completely sequenced. The length of the RNAs are 5889 and 3481 nt, for RNA1 and RNA2, respectively, excluding the poly(A) tails. The two genomic RNAs have no sequence homology apart from at the 5' and 3' termini. Full-length infectious cDNA clones of both RNAs of CPMV have been constructed, allowing the genome to be manipulated.

Expression of the Viral Genome

Both genomic RNAs contain a single long open reading frame (ORF) which occupies over 80% of the length of the RNA. A combination of *in vitro* translation and protoplast studies has unravelled the basic mechanism of gene expression of the virus. Both RNAs are expressed through the synthesis and subsequent cleavage of large precursor polypeptides (Fig. 2). On RNA1, initiation of

Fig. 3 A model for CPMV Assembly. The L (green) and S (blue) subunits associate to form a CP penton. The C-terminal extension of the S protein (pink circle) appears to act as 'molecular glue', stabilizing the formation of the penton due to extensive interactions with the neighbouring S subunit. In the absence of RNA (RNA-free assembly shown in the top half of the diagram), C-terminal cleavage is slow, and eVLPs are produced. Once an extensive protein: protein interaction network is formed, the eVLP structure is stable and no longer depends on the presence of the C-terminal extension. In the presence of genomic RNA, assembly follows a different path (bottom half of the diagram). Initially, pentons are formed in the same way as in the eVLP, using the C-terminal extension for stability. Two pentons interact to form a twofold axis, and thus the RNA-binding site appears to exist at that position. The model shows genomic RNA (represented as an orange rectangle) initially binding to the two pentons at this twofold axis, the first step in genome encapsidation, followed by the stepwise addition of pentons, to form RNA-containing capsids. Reproduced from Hesketh, E.L., Meshcheriakova, Y., Dent, K.C., *et al.* 2015. Mechanisms of assembly and genome packaging in an RNA virus revealed by high-resolution cryo-EM. *Nature Communications* 6, 10113.

translation occurs at the first AUG encountered on the sequence (at position 207) and results in the synthesis of a protein of approximately 200 kDa (the 200K protein). This initial product undergoes rapid co-translational autoproteolysis to give proteins with apparent sizes of 32 kDa (Protease co-factor; ProC) and 170 kDa (170K) proteins. The 170K protein undergoes further cleavages to give the range of virus-specific proteins shown in Fig. 2, specifically the 58K Helicase, VPg, the 24K protease and the 87K polymerase.

Initiation of translation of RNA2 occurs at two different positions on the RNA and results in the synthesis of two carboxy coterminal proteins, the 105K and 95K proteins. This double initiation phenomenon occurs through "leaky scanning". Synthesis of the 105K protein is initiated from an AUG at position 161, while initiation from an in-frame AUG at position 512 directs the synthesis of the 95K protein; RNA-2 also has an additional AUG (position 115) upstream of both these initiation sites but in a different reading frame. Both RNA2-encoded primary translation products are cleaved by the RNA1-encoded 24K protease to give either the 58K or the 48K protein (depending on whether it is the 105K or 95 K protein being processed) and the precursor two viral CPs, VP60, which is then subsequently processed to give the mature L and S CPs. Processing of the RNA2-encoded polypeptides, at least at the site between the 48K and L CP, has been shown to require the presence of the 32K ProC protein as well as the 24K protease.

Functions of the Viral Proteins

Functions have been ascribed to most of the regions of the polyproteins encoded by both RNA1 and RNA2 of CPMV. In most cases, however, it is not certain at what stage(s) in the cleavage pathway they manifest their activity.

In the case of RNA1, the 32K ProC protein, which is rapidly cleaved from the N-terminus of the 200K primary translation product, is a cofactor which modulates the activity of the virus-encoded 24K protease. As described above, the presence of ProC is required for the cleavage of the RNA2-encoded 105K and 95K proteins but is not essential for the cleavage of the RNA1-encoded 170K protein. It does, however, seem to play a role in determining the rate at which cleavage of the 170K protein occurs. When mutant RNA1 molecules carrying deletions in the region encoding ProC are translated *in vitro*, the rate of processing of the 170K protein is greatly increased, indicating that the 32K protein acts as an inhibitor of processing. This inhibition may be achieved through the interaction of the 32K with the 58K Helicase domain of the 170K protein. The mechanism by which the 32K protein enables the 24K proteinase to cleave *in trans* is unclear. It could be due to a direct association between the 32K protein and the 24K proteinase (or an intermediate containing the proteinase domain) or it could be an indirect result of the 32K protein modulating the cleavage of the 170K protein, thereby allowing a 24K-containing intermediate with *in trans* processing activity to accumulate.

The RNA1-encoded 58K Helicase protein is associated with cell membranes and contains a nucleotide-binding motif. A protein containing the aa sequence of the Helicase protein linked to VPg, is involved in rearrangements in the endoplasmic reticulum of CPMV-infected cells and acts in concert with ProC. The 24K protease carries out all the cleavages on both the RNA1- and RNA2-encoded polyproteins. Its proteolytic activity has been shown to be expressed in processing intermediates that contain its sequence. Indeed, it is not known whether the free form of the protein has any biological significance. Although the proteinase contains a

Fig. 4 Diagrammatic representation of the T-DNA region of the transient expression vector, pEAQ-HT showing the polylinker in detail. This polylinker allows the expression of the target protein with or without His-tags. The black boxes represent the T-DNA borders, the green arrows represent promoter sequences and the red arrows represent terminator sequences. The locations of the CPMV RNA2-derived 5' and 3' UTRs, between which the target sequence is inserted, is indicated. Reproduced from Sainsbury, F., Thuenemann, E.C., Lomonossoff, G.P., 2009. pEAQ: Versatile expression vectors for easy and quick transient expression of heterologous proteins in plants. *Plant Biotechnology Journal* 7, 682–693.

cysteine at its active site, it is structurally related to serine proteases, such as trypsin, rather than cellular thiol proteases, such as papain, a feature similar to the 3C proteinases of members of the family *Picornaviridae*. All CPMV cleavage sites have glutamine (Q) residue at the –1 position.

The 87K Polymerase contains all the sequences associated with it being the virus-encoded RNA-dependent RNA polymerase (RdRp), including the GDD sequence motif found in all such enzymes. It also has aa sequence homology to the 3D polymerases encoded by the picornaviruses. Consistent with this identification, mutation of the GDD motif to GAD or AAA reduces or abolishes replication, respectively. When replication complexes capable of elongating nascent RNA chains were isolated from CPMV-infected cowpea plants they were found to contain the 110K protein (Fig. 3), consisting of the sequence of 87K polymerase protein linked to the 24K proteinase, rather than the free 87K protein, and this 110K protein is often referred to as the viral “replicase”.

In the case of RNA2, the 48K protein, derived from processing of the 95K protein, is involved in potentiating the spread of the virus from cell to cell. This protein is found in tubular structures that are formed in the plasmodesmata of infected cells. Tubules extending into the culture medium can also be seen in protoplasts either infected with CPMV or transiently expressing the 48K protein. Virus particles can be seen within these tubules when protoplasts are infected with CPMV but not when only 48K protein is expressed. At present, no definite role has been assigned to the 58K protein which is produced by processing of the 105K protein. Elimination of AUG161, preventing production of the 105K protein, results in a substantial reduction of RNA2 replication. The mature viral CPs, L and S, are produced by cleavage of VP60 by the 24K protease. As well as protecting the genomic RNAs, capsid formation is essential for the virus to be able to spread from cell to cell through modified plasmodesmata and long-distance movement also requires capsid formation. An additional function in suppressing gene silencing is also provided by the C-terminal region of the S protein.

Replication

CPMV replicates to high level in infected cells. Replication is believed to involve the initial transcription of the incoming positive-sense RNA into minus-strands followed by initiation and synthesis of new plus-strands from the recently formed minus-strands. It has been shown that the 5' ends of both the plus- and minus-strands are covalently linked to the VPg, suggesting that this protein has an essential role in the initiation of RNA synthesis. There also appears to be a tight linkage between the translation of the viral RNAs and their replication and between replication and the encapsidation of the viral RNAs.

Replication of the viral RNAs has been shown to occur in the membranous cytopathological structures which are formed in the cytoplasm of cells during infection through the action of the RNA1-encoded 32K and 60K proteins. Both CPMV-specific double-stranded replicative form (RF) RNA and an enzyme activity capable of completing nascent RNA strands can be isolated

from such structures. Purified preparations of the enzyme activity contain the RNA1-encoded 110K replicase and two host-encoded proteins of 68 and 57 kDa. However, at present no enzymatic activity capable of initiating RNA synthesis *in vitro* has been described.

Use in Biotechnology

CPMV particles have been extensively used in bio and nanotechnology. In the first instance, antigenic peptides (epitopes) were genetically fused to exposed loops on the surface of the viral capsids using sites within both the L and S CPs. The resulting chimeric virus particles could be propagated in plants and the modified virions purified, provided the inserted peptide was not too long or excessively positively-charged. When injected into experimental animals, the modified particles could elicit the production of antibodies against the inserted epitope and in several instances were shown to confer protective immunity against the pathogen from which the epitope was derived. In addition to genetic modification, it is possible to chemically attach compounds to the surface of the particles via addressable aa such as lysine, glutamic and aspartic acid. Chemical attachment has the advantage that it allows moieties other than aa to be displayed on the surface of particles. It has also proved possible to combine both genetic and chemical methods to enable the mineralisation of virus particles. The development of a system for the production of eVLPs has also enabled CPMV particles to be loaded with foreign materials, such as drugs and heavy metals. The eVLPs have also proven useful for the selection of affimers which can subsequently be used to diagnose CPMV infections.

CPMV RNA2 has been extensively used as a gene vector for the expression of heterologous proteins in plants via transient expression. Initially, such applications relied on the ability of the modified RNA to be replicated by RNA1 to achieve high level expression. However, the deployment of suppressors of gene silencing and the removal of inhibitory AUG codons, coupled with efficient agro-infection technology, has led to the development of a series of RNA2-based expression vectors (the pEAQ series) that do not rely on replication. In this system, the gene to be expressed is positioned between a modified version of the RNA2 5'UTR, lacking the AUG codons upstream of AUG512, and the RNA2 3'UTR to create a synthetic mRNA cassette (Fig. 4). Transcription of the cassette is driven by the Cauliflower mosaic virus 35S promoter and terminated by the nos terminator. The whole transcription unit is placed between the left and right T-DNA borders within a binary plasmid together with a transcription unit for the P19 suppressor of gene silencing. Agro-infiltration is used to deliver the plasmids to plant tissue and expression is usually detected within one week.

The pEAQ expression system has been used for the expression of a wide variety of different proteins, including those capable of forming VLPs and enzymes for bio-transformations. The elimination of the need for replication means that it is possible to co-express multiple proteins within the same cell, thus allowing the manipulation of biosynthetic pathways.

Glossary

Cross-protection Inhibition of systemic virus accumulation and disease by prior inoculation of plants with a mild or symptomless strain of the same virus.

Filiformism Narrowing of the leaf blade, often leading to symptoms referred to as shoestring.

Non-circulative A mode of virus transmission in which the virus does not need to circulate through the vector digestive system, hemocoel or salivary glands. The virus is carried by attachment to the mouthparts or foregut of the vector.

Non-persistent A mode of virus transmission characterized by short acquisition and inoculation times (from seconds to minutes).

Pseudo-recombination Reassortment of the genomic segments of two or more strains of a virus to generate novel combinations of the full complement of genomic segments.

Reassortant A virus resulting from reassortment (or pseudo-recombination), *i.e.*, exchange of entire genome segments between two or more parental strains.

Satellite RNA A subviral RNA dependent on a helper virus for both replication and encapsidation.

Tonoplast The membrane surrounding the central vacuole of plant cells.

Virulence The impact of a parasite on its host's health or fitness.

Yellowing Light green symptoms induced by virus infection affecting chlorophyll accumulation.

Introduction

Cucumber mosaic virus (CMV) is the type species of the genus *Cucumovirus* in the family *Bromoviridae*, a group of single-stranded positive-sense RNA viruses. It was first described in 1916 as a disease of cucurbits in the USA. CMV has a worldwide distribution and a host range of over 1000 plant species. CMV is one of the most important agronomic pathogens on vegetable and ornamental plants as well as some important fruit crops. The virus is transmitted horizontally by about 80 aphid species in a non-persistent and non-circulative manner. In some plants, CMV is also transmitted vertically through the seed with variable, but usually low, efficiencies. CMV has a segmented genome and is multipartite, meaning that the three main genomic RNAs are encapsidated in separate particles (virions). CMV virions are isometric particles of 29 nm in diameter ($T=3$ symmetry). The CMV genome encodes five proteins. The 1a and 2a proteins are involved primarily in virus replication occurring on tonoplast membranes, while the 2b, 3a, and 3b proteins are involved in virus cell-to-cell or systemic movement. The 2b protein is one of the best studied viral suppressors of plant defenses based on RNA silencing. Over 100 years of research on this agronomically important pathogen have yielded much knowledge on diverse aspects of virus biology, from epidemiology, ecology and evolution to the molecular mechanisms involved in virus-host interactions. Different isolates of CMV induce a variety of disease responses, which are attenuated by a satellite RNA (satRNA) associated with some isolates of CMV, although some satRNAs can enhance pathogenicity. Control of CMV is principally based on sanitary selection, prophylactic measures and use of resistant plant cultivars.

Fig. 1 Schematic topology of phylogenetic trees representing CMV genetic diversity from full-genome sequences. Whereas numerous isolates from subgroups IA and IB and group II have been entirely sequenced (indicated by gray triangles), only one or two isolates of group III or outliers (isolates Rom from rosemary, 209 from soybean and BX and PHZ from *Pinellia ternata*) have been sequenced. Only branches supported by bootstrap values >70% are depicted (branch lengths are not at scale). The tree was rooted with other members of the genus *Cucumovirus*.

Taxonomy and Phylogeny

CMV isolates differ from members of the other three species in the genus *Cucumovirus*, *Tomato aspermy virus* (TAV), *Peanut stunt virus* (PSV) and *Gay feather mild mottle virus* (GMMV), having only 50%–67% nt sequence identity, depending on the RNA and isolates being compared. Isolates of CMV are heterogeneous in symptoms, host range, transmission, serology, physicochemical properties, and nucleotide sequence of the genomic RNAs. CMV isolates can be classified into two major genetic groups, I and II. The nt identity between isolates belonging to these groups ranges from 69% to 77%, depending on the pair of isolates and the RNA segment compared, dissimilarity being highest for RNA2. Within a group, nt identity is above 88% for group I and above 96% for group II. Isolates of groups I and II can also be distinguished using monoclonal antibodies. RNA2 sequences of group I CMV isolates correspond to two monophyletic subgroups named IA and IB (Fig. 1). Subgroup IA, but not subgroup IB, is also monophyletic for RNA3, while RNA1 shows no clear division into subgroups IA and IB. This indicates that the different genomic segments have followed different evolutionary histories. Cross-protection occurs between isolates from all groups or subgroups. A few CMV isolates do not belong to groups I or II (Fig. 1).

Geographic Distribution

CMV isolates have a worldwide distribution, having been reported from both temperate and tropical regions. Most reported isolates belong to group I. Group II isolates are found more frequently in cooler areas or seasons of temperate regions. This has been associated with lower temperature optima for *in planta* virus accumulation shown for the few isolates characterized for this property. Most isolates in subgroup IB have been reported from East Asia, which is presumed to be the origin of this subgroup. Subgroup IB isolates have also been reported from other areas, for example, the Mediterranean region, California, Brazil, Africa and Australia. Those in the Mediterranean Basin could have been introduced recently from East Asia.

Host Range

Considering all isolates collectively, the host range of CMV includes 1071 plant species belonging to 100 different families, monocot or dicot. Of these plants, more than 500 species were found infected naturally, whereas the others were only found infected in laboratory conditions. Four families include more than 100 host species each: the *Solanaceae*, *Asteraceae*, *Fabaceae* and *Brassicaceae*. CMV infects most of the major horticultural crops as well as many weed species acting as reservoirs for the virus. However, considerable differences in host range breadth exist between individual CMV isolates. Most isolates have a broad host range while a few isolates have a very narrow host range, like certain isolates from soybean, lily or rosemary. These ‘soybean’ and ‘rosemary’ isolates, as well as isolates from *Pinellia ternata*, are phylogenetically distant from groups I and II (Fig. 1). Recent evidence has expanded the host range of CMV outside of the plant kingdom: a phytopathogenic fungus, *Rhizoctonia solani*, was described as a natural alternative host for CMV. This non-plant host may have an important impact on epidemiology of the disease, since the fungus could acquire CMV from an infected plant and transmit it to a healthy plant under laboratory conditions.

Symptoms and Diagnosis

Symptoms induced by CMV include leaf mosaic or mottling, vein-clearing, filiformism (the shoestring appearance of the leaf blade, a typical CMV symptom on tomato leaves), stunting, chlorosis and necrosis (including necrotic “oak-leaf” symptoms on older leaves) as well as decreased fruit or seed yield (Fig. 2). Pepper and cucurbit fruits, among others, can display symptoms such as mottling, mosaic, ring spotting or deformations. Symptom type and severity can vary greatly depending on the host species, the particular combination of plant and virus genotypes, the phenological stage at the time of infection, environmental conditions, as well as the presence of other

Fig. 2 Symptoms associated with CMV infection. (A) CMV-induced symptoms in a pepper field. (B) Mosaic symptoms on tobacco leaves infected with CMV I17F isolate (belonging to the IA subgroup). biotic factors such as satRNAs and other viruses, which can modulate the disease symptoms induced by CMV. CMV infection can also be symptomless. This is the case in many weed species which can serve as asymptomatic CMV reservoirs.

Host species which are systemically infected by most CMV isolates and commonly used as indicator plants include squash (*Cucurbita pepo*), cucumber (*Cucumis sativus*), tobacco (*Nicotiana tabacum*), as well as *N. benthamiana*, *N. clevelandii*, and *N. glutinosa*. *Chenopodium amaranticolor*, *C. quinoa* and cowpea (*Vigna unguiculata*) are local lesion hosts.

Serological methods like enzyme-linked immunosorbent assay (ELISA) have been successfully used for the large scale detection and diagnosis of CMV. Although molecular methods like reverse transcription-polymerase chain reaction (RT-PCR) are more sensitive, since CMV usually accumulates to high levels in infected plants, it is readily detected using ELISA, which makes this serological assay the method of choice for detecting CMV in plant samples. Another widely used serological diagnostic method is the lateral flow test (immune-strip tests based on this method are commercially available). Although lateral flow tests are relatively expensive, they constitute a rapid means of screening crops for the presence of CMV, particularly adapted for diagnostics in the field or greenhouse.

Cytopathology

Cytopathology associated with infection by CMV includes viral inclusions within the cytoplasm and vacuoles, or forming membrane-bound clusters in sieve elements. In some cases, angular inclusions corresponding to virus crystals can be seen in vacuoles by staining and light microscopy. CMV infection usually also leads to proliferation of cytoplasmic membranes, which originate from the plasma membrane, the endoplasmic reticulum (ER), or the tonoplast. Effects on the nucleus or nucleolus (e.g., vacuolation), usually due to virion accumulation, have been observed with some isolates of CMV. Similarly, some isolates have caused effects on mitochondria or chloroplasts. Yellowing isolates, in particular, lead to smaller and rounded chloroplasts that have fewer grana and starch granules. These various effects appear to be host specific. How virus-plant interactions lead to cytopathic effects remains unknown; however, as the virus expands from the initial site of infection, rings or zones of responses occur, in which the expression patterns of numerous plant genes are altered in spatial- and temporal-specific manners.

Virion Structure

Transmission electron microscopy observations allow visualization of the uniform isometric (roughly spherical) particles of CMV. The atomic structure of CMV has been determined to a 3.2 Å resolution using X-ray crystallography. CMV virions are icosahedral particles 29 nm in diameter. They are composed of 180 subunits of a single capsid protein (CP) of approximately 24 kDa, and contain approximately 18% RNA. RNA-protein interactions stabilize the virions and particle assembly requires a nucleic acid as a nucleating factor (no empty particles are formed). Virions are disrupted by sodium dodecyl sulfate and concentrated chloride salts, but can be

Fig. 3 Cryo-transmission electron microscopy reconstruction of CMV particles. Icosahedral CMV virions are composed of 12 pentamers and 20 hexamers. Reproduced from Wikoff, W.R., Tsai, C.J., Wang, G., Baker, T.S., Johnson, J.E., 1997. The structure of cucumber mosaic virus: Cryo-electron microscopy, X-ray crystallography, and sequence analysis. *Virology* 232 (1), 91–97.

Fig. 4 Schematic representation of the genome organization of CMV. The CMV genome is composed of 3 genomic RNAs, RNAs 1, 2, and 3 encoding 5 proteins. Two sub-genomic RNAs, RNAs 4A and 4 are transcribed from the minus RNA2 and RNA3 strands, respectively. The open reading frames are depicted as colored bars. The approximate length of the RNAs are indicated. nt, nucleotides; sgRNA, sub-genomic RNA; MP, movement protein; CP, capsid protein.

reassembled *in vitro* by removing salts or sodium dodecyl sulfate. Each CP subunit adopts a canonical β -barrel structure, and all subunits assume one of three different configurations (A, B, or C). The A subunits cluster to form pentameric capsomers (or pentamers) and the B and C subunits form hexameric capsomers (or hexamers). The capsid is composed of 12 pentamers and 20 hexamers arranged with $T=3$ symmetry (Fig. 3). The N termini of the B and C subunits form a bundle of six α helices. This hexameric bundle constitutes a hydrophobic pore lined with leucine residues that extends down to the RNA-capsid interface. The first 30 residues of the CP (upstream of the α helix) are rich in positively charged aa, including 7 conserved arginine residues, that are proposed to form the interface with the RNA core. RNAs that can be encapsidated in CMV virions include genomic RNAs 1, 2, and 3, sub-genomic RNAs (sgRNAs) 4 and 4A, RNA5, transfer RNAs (tRNAs), as well as satellite and defective RNAs (see below).

Genome Organization

The genome of CMV consists of five genes distributed over three, single-stranded, positive-sense, capped genomic RNAs designated RNAs 1, 2, and 3 in descending order of size (Fig. 4). CMV is a multipartite virus, meaning that the three genomic RNAs are encapsidated in separate virus particles. RNA1 (~3.3 kb) encodes the 111 kDa 1a protein. RNA2 (~3.0 kb) encodes the 98 kDa 2a protein, as well as the 13–15 kDa 2b protein, which is translated from a ~0.7 kb sub-genomic RNA designated RNA 4A that is co-terminal with the 3' end of RNA2. The Open Reading Frame (ORF) expressing the 2b protein overlaps with the ORF encoding the 2a protein, but in a +1 reading frame. RNA3 (~2.2 kb) encodes the 30 kDa 3a protein, as well as the 25 kDa 3b protein, which is expressed from a ~1 kb sub-genomic RNA designated RNA4 that is co-terminal with the 3' end of RNA3. RNA4 is co-encapsidated with RNA3. The 3' untranslated regions (UTRs) of all three genomic and both sub-genomic RNAs are highly conserved, forming a tRNA-like structure as well as several pseudoknots. The 5' UTR regions of RNA1 and RNA2 are more conserved in sequence with each other than with those of RNA3. CMV also produces an RNA5 of unknown function, which is co-terminal with the 3' UTR regions of RNA1 and RNA2. RNA4A and RNA5 are only encapsidated by group II isolates. CMV

particles also encapsidate a low level of tRNAs, which have been reported in the literature as CMV RNA6. Although rarely reported, some isolates of CMV can also encapsidate defective RNAs derived from CMV RNA3.

CMV can also support satRNAs varying in size from 333 to 405 nt. These satRNAs do not encode any proteins. They are dependent upon CMV as the helper virus for both their replication and encapsidation, but have sequence similarity to the CMV RNAs limited to no more than 6–8 contiguous nts. The origin of satRNAs remains enigmatic. The *de novo* emergence of satRNAs after serial passages of CMV devoid of satRNA in tobacco plants suggests that they may have arisen from the host genome. Failure to detect long satRNA homologs in host plant genomes has led to an interesting hypothesis: that host genome-encoded small RNAs, possibly induced by viral infection, could be assembled by the viral replicase to form satRNAs. More than 180 satellite variants have been found associated with over 65 isolates of CMV from both of the CMV groups. These satRNAs usually reduce the accumulation of the helper viruses and on most hosts also reduce the virulence of CMV. However, certain satRNAs can enhance the disease induced by CMV in some hosts. In the case of tomato plants infected by CMV and certain satellites, this has led to systemic necrosis observed in the fields of several Mediterranean countries.

Properties and Functions of Gene Products

The CMV 1a and 2a proteins contribute to virus replication but also promote virus movement in several host species. The 2b protein is an RNA-silencing suppressor that interferes with the salicylic acid (SA) and jasmonic acid (JA) plant defense pathways and also influences virus movement in some hosts. The predominant mechanism by which the 2b protein inhibits antiviral silencing is by sequestering virus-derived small RNAs. Additionally, the 2b protein binds to Argonaute (AGO) proteins, the catalytic component of the RNA-induced silencing complex (RISC), and inhibits their RNA cleavage activity. The contribution of the 2b-AGO interaction to antiviral silencing is minor, likely through the inhibition of signal amplification mediated by host RNA-dependent RNA polymerases (RdRps). Conversely, the 2b-AGO interaction plays an important role in the induction of developmental symptoms, through the disruption of microRNA- (miRNA) mediated post-transcriptional gene silencing. The 3a protein is the major movement protein (MP) of the virus and is essential for both cell-to-cell and long-distance (systemic) movement. The 3b protein is the sole viral CP and is also required for cell-to-cell and systemic movement, although the ability to form virions is not a requirement for intercellular trafficking of the virus. All of the CMV-encoded proteins are RNA-binding proteins. Viral RNAs from different groups and subgroups can be exchanged to form novel viruses, allowing mapping of some phenotypes to specific RNAs. Higher-resolution mapping requires the use of biologically active cDNA clones for generating chimeras and site-directed mutants. By these approaches, a large number of genetic determinants of pathogenicity or transmission have been mapped ([Table 1](#)). All CMV RNAs and genes can be involved in infection and symptomatology, depending on the plant species or genotype.

The biochemical mechanisms responsible for the variety of symptoms induced by CMV have rarely been determined. In the case of an isolate of CMV that induces chlorotic symptoms in tobacco, interaction of the virus CP with the ferredoxin I protein precursor interferes with its import into the chloroplast and is therefore responsible for the symptoms.

Moreover, particular satRNAs can also contribute to CMV symptomatology, sometimes causing an attenuation of symptoms, a property that has been used commercially in tomato production. Attenuation of disease appears to result from the production of satellite-derived small interfering RNAs (siRNAs) that can either directly target the conserved 3'UTR region of the CMV genomic RNAs and trigger their degradation through the host RNA silencing machinery or interfere with the RNA silencing suppressor activity of the 2b protein by binding to it.

The CMV Infection Cycle

Replication

CMV replication takes place on the vacuole membrane (the tonoplast). Replication involves the 1a and 2a proteins of the virus and a number of host proteins. The purified CMV replicase contains the 1a and 2a proteins, as well as a 50 kDa host protein of unknown function. The 1a protein of CMV contains an N-terminal methyltransferase domain involved in capping of the RNAs, as well as a putative C-terminal helicase domain, presumed to be required for the unwinding of the viral RNAs during replication. The 2a protein possesses a GDD (Glycine-Aspartic acid-Aspartic acid) motif found in most RdRps. The N-terminal region of the 2a protein interacts with the C-terminal region of the 1a protein *in vivo* and *in vitro*. CMV replication is initiated by the binding of the tonoplast-associated replicase to the tRNA-like structure and various pseudoknots present in the 3'UTR region of the positive-sense CMV RNAs. Minus-sense RNAs are then synthesized from each of the genomic RNAs and act as templates for synthesis of new plus-stranded genomic RNAs. The minus-sense RNA2 and RNA3 also serve as templates for the synthesis of the two plus-sense sub-genomic RNAs (4 and 4A), through recognition of the sub-genomic promoters present on the minus-sense RNAs. The sub-genomic RNAs are not themselves replicated, but defective and satellite RNAs are replicated by the CMV replicase. Differences in the relative levels of accumulation of the various CMV genomic and satellite RNAs have been observed in different host species, which is probably due to host-specific differences in template copying.

Like most plant viruses, CMV encodes a very small number of proteins and relies on plant host factors to fulfill the different steps of its infection cycle. CMV replication is intricately dependent on various host proteins. Several host factors which support or

Table 1 Molecular determinants of pathogenicity and transmission identified in CMV

Phenotype	Plant	Genome region	Mutation (codon)
Symptoms			
Chlorosis, mosaic, or necrosis	<i>Nicotiana tabacum</i>	CP gene	129, 111, 124
Green mosaic, yellow chlorosis	<i>Nicotiana</i> spp.	CP gene	111, 124
Top necrosis	<i>Nicotiana glutinosa</i>	2b gene alone or 2b and 2a genes	
Necrotic etch	<i>N. tabacum</i>	RNA 3 (5' UTR and/or MP gene)

restrict virus multiplication have been identified (Table 2). Although the exact roles of these proteins in virus replication are not always clear, they are proposed to act through regulation, assembly and/or anchoring of the CMV replication complex to the tonoplast. One such protein is glyceraldehyde 3-phosphate dehydrogenase (GAPDH) which is critical for CMV replication and appears to be involved in assembly of the viral replication complex by promoting the interaction between the 1a and 2a proteins.

Comparatively, very few plant factors involved in cell-to-cell or systemic propagation of the virus have been identified (see below and Table 2) although CMV presumably co-opts a number of host factors for these steps of its infection cycle.

Post-translational modifications of viral replication proteins play an important role in the regulation of CMV replication. For example, phosphorylation of the 2a protein prevents its association with the 1a protein and thus regulates assembly of the replicase complex. This mechanism probably plays an important role in the regulation of plus-strand and minus-strand synthesis and the asymmetry of CMV replication. Indeed, the kinetics of accumulation of positive and negative strands are distinct and accumulation of CMV positive strand RNAs is approximately 100-fold that of negative strand RNAs. Free 2a protein is present in the cytoplasm, while the 1a protein is strictly membrane-associated. The 2a protein alone is sufficient to synthesize positive strands from negative strand templates, while both the 1a and 2a proteins are required for synthesis of negative strands. Therefore the switch from negative to positive strand synthesis may be controlled by 2a phosphorylation, resulting in dissociation of 1a-2a complexes.

Positive-sense viral RNAs serve as templates for replication and translation of viral proteins and are encapsidated to form virions. The balance between replication, translation, encapsidation and probably also movement of these viral RNAs determines the efficiency of virus multiplication.

Cell-to-Cell and Long-Distance Movement

CMV moves cell to cell via plasmodesmata until it reaches the vasculature, when the virus moves systemically via the phloem. The viral RNAs move as a nucleoprotein complex between cells involving the 3a MP. Although the virus does not appear to migrate as virus particles, the CP is also necessary for cell-to-cell movement. This movement does not involve interactions with microtubules. Conversely, the actin cytoskeleton appears to be involved in CMV cell-to-cell movement (Table 2). The MP has been shown to interact with and sever actin filaments, an activity associated with increase of the plasmodesmal size exclusion limit. CMV appears to move between epidermal cells as well as from epidermal cells down to mesophyll cells toward vascular cells. The virus replicates in all of these cell types, but not in the sieve elements of the vasculature. Long-distance movement includes three main steps: viral loading into the phloem tissues, movement within sieve elements, and unloading from these elements into cells of the sink tissues. Virion assembly may take place inside sieve elements from RNAs and capsid protein moving from neighboring vascular cells. Virion assembly is necessary in some, but not all, species for systemic infection. A 48 kDa phloem protein (PP1) from cucumber phloem exudates interacts with CMV particles *in vitro* and increases virus particle stability. How the virus moves from the vasculature back to mesophyll and epidermal cells is unknown.

The 2b protein is also involved in local and systemic movement of the virus. The 2b protein has indirect effects on virus movement through its RNA silencing suppressor activity, as well as direct effects on cell-to-cell movement, independently of this suppressor activity, as has been revealed in an alanine scanning mutagenesis study that identified residues in the 2b protein that are required for local movement but not for silencing suppression.

The elucidation of resistance mechanisms targeted against systemic spread of CMV is revealing some of the probably manifold resistance barriers preventing long-distance movement of the virus. For example, a Piezo-like mechanosensitive cation channel which suppresses systemic spread of CMV has been identified in the model plant *Arabidopsis* (see also in the "Control" section the molecular mechanisms involved in resistance conferred by the *cmv1* resistance gene in melon). Conversely, other host proteins like Tco1 (tobacco CMV 1a-interacting protein 1) promote systemic spread of the virus (Table 2).

Plant proteins that are essential to the virus infection cycle can serve as targets to screen the plant natural genetic diversity in order to identify resistance alleles or to engineer new resistances, using technologies such as CRISPR/Cas9 (Clustered Regularly Interspaced Short Palindromic Repeats/CRISPR associated protein 9) genome editing or TILLING (Targeting Induced Local Lesions in Genomes).

Transmission

Seed transmission of CMV has been reported in 41 plant species, mostly in the families Fabaceae (26 species) and Cucurbitaceae (seven species), with efficiencies varying from less than 1% up to almost 100%. The virus may be present in the embryo, endosperm, and seminal integuments, as well as in pollen. RNA1, possibly *via* the encoded protein 1a, affects the efficiency of seed transmission. Horizontal transmission of CMV is mediated by aphids (family *Aphididae*) in a non-persistent and non-circulative manner. This mode of virus transmission (also called stylet-borne) is characterized by short acquisition and inoculation times (from seconds to minutes). The stylets of the aphid become contaminated with the virus during probing of infected tissue, through a series of short intracellular stylet punctures of epidermal or neighboring cells. The virions are retained at sites at the tip of the aphid stylet, and released by salivation during probing of non-infected plants. Over 80 species of aphids have been reported to transmit CMV, *Aphis gossypii* and *Myzus persicae* being two efficient and most studied vectors. Transmission efficiency depends on several factors, particularly the specific combination of virus isolate and aphid species, and the

accumulation of particles in the source leaf. Differences in transmissibility of various isolates by different aphid species are determined primarily by the virus coat protein and aa determinants for transmission have been mapped (**Table 1**). The aa positions that determine transmission are either exposed on the outer surface of capsids (e.g., aa position 129) or lay in the inner surface (e.g., position 162). Hence, the effect could be through direct interaction with receptors in the aphid mouth parts or by affecting particle stability. On the vector side, there is accumulating evidence for the role of cuticular proteins of the CPR (cuticular proteins with the Rebers and Riddiford Consensus) family in the transmission of plant viruses. Putative CMV receptors belonging to this family are present in the acrostyle, a small structure inside the fused food/salivary common canal at the tip of aphid stylets. One of these proteins has been shown to act as a probable caulimovirus receptor. However, there is no direct evidence of binding of CMV in the common canal, and validating the role of these cuticular proteins in CMV transmission will require further biochemical and functional studies.

The 2b protein of CMV also seems to have an indirect effect on virus transmission by manipulating the behavior of aphids. By altering the jasmonate signaling pathway and increasing the plant reactive oxygen species content, the 2b protein simultaneously enhances attractiveness of host plants for aphid vectors and increases probing and dispersal of the aphids, thus favoring spread of the virus.

Transmission efficiency also depends on the host plant, as shown by the resistance to transmission of melon genotypes carrying the *Vat* gene, which does not confer resistance to the virus directly, but impairs CMV transmission by *Aphis gossypii*.

Variation and Evolution

CMV populations share evolution patterns of many plant RNA viruses, including high mutation rates and high intensities of selection and genetic drift. Moreover, phylogenetic analysis showed that recombination and particularly reassortment have largely contributed to the diversification of CMV populations, as seen in other viruses with segmented genomes. Using infectious cDNA clones and experimental evolution, CMV mutation and recombination frequencies were estimated. Mutation frequency varied from 0.6×10^{-4} to 1.8×10^{-3} mutation per nt in a 12–15 days passage in plants. Significant differences in mutation frequency were observed between plant species and between CMV isolates. The recombination frequency was also highly variable between isolates. Indeed, depending on the parental isolates, from 1.8% to 28.2% of RNA3 recombinants were observed 15 days after inoculation with parental CMV clones. The 2a gene is a major determinant of recombination frequency differences. Recombination also seems to be facilitated by stem–loop structures in the RNA. The 3' UTR of CMV genomic RNAs is also a recombination hotspot. Recombinants in this region may have an increased fitness in some hosts, as shown for isolates infecting *Alstroemeria* spp. However, analyses of field populations of CMV show that recombinants are not frequent, suggesting that selection operates against most of them. A second mechanism of genetic exchange is reassortment of genomic segments also called pseudo-recombination. Reassortants exchanging any genomic segment have been obtained between different CMV isolates and multiply efficiently under experimental conditions. Natural CMV reassortants also have been described but are generally rare and seem to be selected against, as is the case for recombinants, which suggests co-adaptation of the different viral genes that, when disrupted, results in a decreased fitness. However, reassortants may reach higher frequencies as shown in pepper (*Capsicum* spp.) crops in Tunisia and South Korea, where they comprised 90% and 20%, respectively, of the CMV populations. Selection by the host plant and possibly by resistant cultivars may be responsible for this over-representation of reassortants.

Genetic diversity of CMV has been shown to be countered by genetic drift associated to population bottlenecks during plant colonization and horizontal transmission by aphids. For the latter, from one to two CMV infectious units are inoculated by a single aphid. Selection is also an evolutionary force that drastically restricts the diversity within virus populations. Sequence analysis have shown different evolutionary constraints for the different viral proteins. Protein 1a and the MP are the most constrained, whereas the 2b protein is the least constrained. The evolution constraint acting on the CP differs greatly between CMV groups and subgroups. Positively-selected aa positions have been detected in all CMV proteins and may be responsible for CMV adaptation to host plants or to the vector.

Analyses of the population structure of CMV in Spain and California indicate a metapopulation structure, with local extinctions and recolonizations, which suggests that population bottlenecks occur, probably associated with unfavorable seasons for the host plants and/or the aphid vectors. Interestingly, this is not the case for the population structure of the satRNA. Analyses in Italy and Spain during epidemics of CMV and the associated satRNAs have shown that the satRNAs have an undifferentiated population. The different population structures for CMV and its satRNAs indicate that the satRNAs expanded as a molecular parasite on the CMV population, rather than satellite expansion was linked to a particular CMV isolate.

Epidemiology and Control

CMV infects a wide range of food crops, ornamentals and wild plant species. Economic losses in crops are highest in field-grown vegetables and ornamentals, pasture legumes and banana. In recent times, CMV has caused severe epidemics in many crops, including necrosis of tomato in Italy, Spain, and Japan; mosaic and heart rot of banana worldwide; mosaic of melons in California and Spain; mosaic of pepper in Australia, California, Turkey and Tunisia; and mosaic of lupins and other legumes in Australia and the USA.

As for many plant viral diseases for which there are no curative methods, control of CMV begins with sanitary selection, planting or sowing virus-free material and prophylactic measures. In crops in which seed transmission is effective (e.g., pasture or fodder legumes), the primary inoculum for epidemics may be the seedlings from infected seeds and even a low frequency of seed infection may have dramatic consequences because of accelerated secondary spread of the virus. In most vegetable and ornamental crops, seed transmission does not occur or is negligible, and the primary inoculum must come from outer sources as other crops or weeds, which should be near the crop as aphid transmission is non-persistent. In the absence of crops during unfavorable seasons, infected perennial weeds or crops, and infected seeds from weeds act as inoculum reservoirs. Seed transmission has been shown to be important in several weed species from different regions. The dynamics of virus infection may differ largely in weeds and crops within a region, indicating that the relevant reservoirs and inoculum sources for crops need not be the most frequently infected weeds. In banana, secondary spread of infection within the crop is ineffective for most isolates, and alternative hosts are both primary and secondary inoculum sources for epidemics. Since many species of weeds act as reservoirs for the virus and many of these are asymptomatic hosts, it is important to remove them from the borders of fields. This also applies to removal of infected crop plants during the growing season.

A number of agricultural practices can be implemented to reduce CMV epidemics. For example, avoiding overlap of the growing cycles of CMV-susceptible crops, adapting sowing or planting dates in order to create a lag time between peaks of aphid flights and the susceptibility period of crop plants and using cultivar or crop mixing to benefit from inoculum dilution and barrier effects can slow down CMV epidemics. The use of mineral oils or reflective mulches can also affect aphid behavior and contribute to CMV control.

Table 3 Characteristics of CMV resistance genes or loci

Plant	Gene or allele name	Nature of encoded protein	Resistance mechanism
<i>Arabidopsis thaliana</i>	<i>RCY1</i>	NLR	HR
<i>Capsicum annuum</i>	<i>Cmr1</i>	–	Inhibition of systemic movement
<i>C. annuum</i>	<i>cmr2</i>	–	Inhibition of cell-to-cell movement
<i>C. annuum</i>	Several QTLs	–	Inhibition of infection, virus multiplication and systemic movement
<i>Capsicum frutescens</i>	At least 2 recessive genes	–	Inhibition of cell-to-cell and systemic movements
<i>Cucumis melo</i>	<i>cmv1</i>	VPS41	Inhibition of systemic movement of group II strains
<i>C. melo</i>	<i>Vat</i>	NLR	Resistance to <i>Aphis gossypii</i> -mediated inoculation
<i>Cucumis sativus</i>	Several QTLs or 1 recessive gene	–	Symptom attenuation
<i>Cucurbita moschata</i> , <i>Cucurbita pepo</i>	<i>Cmv-2</i>	–	High-level resistance
<i>Glycine max</i>	Three QTLs	–	Inhibition of systemic movement
<i>Lupinus luteus</i>	<i>Nam-1</i>	–	HR
<i>Nicotiana tabacum</i>	Several QTLs	–	Inhibition of infection, symptom attenuation
<i>Phaseolus vulgaris</i>	<i>RT4-4</i>	NLR	HR
<i>Solanum chilense</i>	<i>Cmr</i>	–	Symptom attenuation
<i>Solanum habrochaites</i>	polygenic	–	Tolerance to satRNA-induced lethal necrosis
<i>Solanum tuberosum</i>	Single major gene	–	Inhibition of systemic movement
<i>Vigna unguiculata</i>	<i>Cry</i>	–	HR
<i>Zea mays</i>	Single dominant gene	–	HR

Abbreviations: HR, hypersensitive reaction; NLR, nucleotide-binding and leucine-rich repeat-containing protein; QTL, quantitative trait locus; satRNA, satellite RNA; VPS, vacuolar protein sorting; –, unknown data.

Control of CMV can also be achieved by planting of resistant crop varieties. Genetic resources for CMV resistance are available in many crop species and their genetic determinism has been unraveled in a few of them (Table 3). However, there is generally a lack of high-level resistance and of major-effect resistance genes against CMV. A large number of resistance mechanisms are polygenic, which hampers their exploitation by breeders, and partial. They frequently slow down the systemic movement of the virus and reduce symptoms. Some of them are ontogenic, *i.e.*, they are only expressed when plants achieve a given developmental stage. Their spectrum of action is also frequently incomplete and covers a few CMV isolates or isolate groups.

A novel mechanism has been discovered for the resistance conferred by the *cmv1* gene in *Cucumis melo*. *cmv1* inhibits CMV systemic infection by restricting the virus to the bundle sheath cells and impeding its loading into the phloem. *cmv1* was cloned and shown to encode a novel class of resistance factors, the Vacuolar Protein Sorting 41 (VPS41) which is required for post-Golgi vesicle trafficking towards the vacuole. CMV might use VPS41 for its transport towards the phloem and a single aa mutation in the protein abolishes or reduces this transport and converts the VPS41 gene into a recessive resistance gene. However, the resistance is efficient only against group II CMV isolates, which reduces its agronomical interest.

In pepper (*Capsicum* spp.), several resistance sources and mechanisms have been described and exploited to breed resistant cultivars. In France, cultivars carrying a polygenic resistance were bred using a recurrent selection program involving several parental lines with different partial resistance mechanisms (inhibition of inoculation efficiency, decrease of virus multiplication and inhibition of systemic movement). Whereas all resistance sources were partial, the composite resistance resulting from the combination of these mechanisms is almost total. The resistance was efficient and durable in the field but is threatened by adapted CMV isolates, belonging to the IB subgroup, that have been introduced in the Mediterranean basin. In South Korea, the major-effect dominant resistance gene *Cmr1* was used in breeding programs and deployed in the field. It inhibits the systemic movement of CMV. However, as in the previous case, it is impaired by subgroup IB isolates. The *cmr2* recessive resistance gene seems to possess a broader spectrum of action and may be a valuable resource for resistance breeding in pepper.

In addition to resistance, mechanisms of plant tolerance against CMV have also been studied. Tolerance is defined as the ability of the host to limit the damage caused by a given virus load, as opposed to resistance, which is the capacity of the host to reduce virus load. Tolerance to CMV has been studied in detail in the model plant *Arabidopsis thaliana* but has also been observed in several agronomically important plants, including bean, cucumber, pepper and tomato. The effect of infection by different CMV isolates on biomass and viable seed production of different *Arabidopsis* accessions was evaluated. Tolerance to different CMV isolates was higher in accessions with longer life cycles and was associated with resource reallocation from growth to reproduction. This tolerance response is CMV-specific as it was not observed in response to infection by other more virulent viruses. Whether similar tolerance mechanisms exist in cultivated plants remains to be determined. As it exerts a weaker selection pressure on virus populations, tolerance is expected to be more durable than resistance. Thus, whatever the mechanisms involved, breeding CMV tolerant crops is a potential source of sustainable protection against CMV.

Other sources of resistance include the use of transgenic plants expressing either protein-mediated or RNA silencing-mediated resistance. Although most of these approaches have led to resistance to only members of one of the two major groups, the use of

pyramiding of viral segments from different groups offers the promise of obtaining a broad-spectrum resistance to CMV together with other viruses infecting the same crop species. Transgenic expression of satRNAs has also been used to confer resistance to CMV. This has met with success, but has raised concerns about favoring the emergence of a virulent pathogen, as did the use of mild isolates of CMV for cross-protection against severe isolates.

The use of insecticides to control the aphid vectors of the virus has met with only limited success, since the virus is transmitted in a non-persistent manner and thus the aphids can transmit the virus before being killed by the insecticide. Rather, insecticides are used to reduce aphid population size and thus reduce the spread of infections. Similar results were obtained through the biological control of aphid populations by the use of predators.

ssRNA Single-stranded RNA
UTR Untranslated region
VRC Viral replicase complex

Glossary

Dicer Eukaryotic ribonuclease that cuts long dsRNAs and structured ssRNAs into ~20–25 bp fragments with 2-nt 5' extensions.

Frameshift A change of the reading frame, which results in a different translation and a different protein product.

Plasmodesmata (Singular: plasmodesma), channels traversing the plant cell walls, allowing for the cell-to-cell transport of substances. Plasmodesmata are internally coated by the endoplasmic reticulum.

Silencing suppressor (Suppressor of silencing): virally encoded proteins from diverse families that interfere with host production or effectiveness of small RNAs.

Introduction

The members of the family *Tombusviridae* have uncapped, single-stranded, positive-sense RNA [(+)ssRNA] genomes. The family *Tombusviridae* can be subdivided into three subfamilies: *Calvirusirinae*, *Procedovirinae*, and *Regressovirinae*. The subfamily *Regressovirinae* contains the genus *Dianthovirus*, the members of which have icosahedral virions and a genome consisted of two (+)ssRNA molecules. Although two genomic RNAs share viral and pro-viral host factors during infection, they exploit different strategies to regulate their translation, transcription, replication, packaging, and cell-to-cell movement.

Taxonomy and Classification

Dianthoviruses belong to the family *Tombusviridae* and the subfamily *Regressovirinae*. Of the 16 genera in the family, only the dianthoviruses have bipartite genomes. The genus *Dianthovirus* is composed of three viruses: *Carnation ringspot virus* (CRSV), *Red clover necrotic mosaic virus* (RCNMV), and *Sweet clover necrotic mosaic virus* (SCNMV) (Table 1). *Furcraea necrotic streak virus*, which was provisionally classified as a member of the genus *Dianthovirus*, is now classified as a member of the genus *Macanavirus* in the family *Tombusviridae*. The amino acid (aa) sequence of dianthovirus coat protein (CP) has high homology with those of the tombusviruses and aureusviruses that belong to the family *Tombusviridae*. Interestingly, the aa sequence of dianthovirus RNA-dependent RNA polymerase (RdRP) has higher homology with that of the luteoviruses that belong to the family *Luteoviridae*, than with those of the viruses in the family *Tombusviridae*.

Genome Organization

The genome of dianthoviruses consists of two single-stranded positive-sense RNA {(+)RNA} molecules, RNA1 (3.9 kb) and RNA2 (1.4 kb) (Fig. 1). RNA1 encodes two replication-associated proteins: an auxiliary 27 kDa protein (p27), an N-terminally overlapping 88 kDa RdRp (p88^{POL}); and the 37 kDa CP, which is the building block of the mature virion. A non-coding viral RNA, called SR1f, accumulates during dianthovirus infection. SR1f is generated from the 3'-untranslated region (UTR) of RNA1 through the action of a host 5' → 3' exoribonuclease. The 3'UTR of dianthovirus RNA1 contains a sequence that inhibits 5' → 3' exoribonucleolytic decay in *cis*. SR1f may suppress translation from RCNMV RNA1 and thus could play a regulatory role in infection by dianthoviruses. RNA2 encodes a 35 kDa movement protein (MP), which plays an essential role in viral cell-to-cell movement and systemic spread in plants.

Virions, Transmission, and Epidemiology

Similarly, to the viruses in other genera, members of the genus *Dianthovirus* have icosahedral virions of approximately 35 nm in diameter with *T* = 3 symmetry that consist of 180 CP subunits of approximately 36–37 kDa. RCNMV virions consist of two

Fig. 1 A schematic representation of the dianthovirus genome structure. The genome of dianthovirus consists of RNA1 and RNA2, which lack a 5'-cap structure and a 3'-poly(A) tail. RNA1 encodes an auxiliary replication protein p27 and an RNA-dependent RNA polymerase (RdRp) p88^{pol} which is translated via a -1 ribosomal frameshift mechanism. RNA1 also encodes a coat protein (CP), which is translated from sub-genomic RNA (CPsgRNA). SR1f, a small noncoding RNA, is generated from the 3'-untranslated region (UTR) of RNA1 by a host 5' → 3' exoribonuclease. RNA2 encodes a movement protein (MP) that is required for viral cell-to-cell movement.

distinct types: one contains one copy of each genomic RNA and the other contains four copies of RNA2. The origin of assembly sequence (OAS) is located in the MP coding region of RNA2. The stem-loop (SL) structure formed from the OAS is also known as the transactivator (TA), and is a multifunctional region that is required for the transcription of sub-genomic RNA and the replication of RNA2 (see the sections below that describe gene expression and RNA replication). RNA1 does not have an independent packaging signal and is co-packaged with RNA2 through an interaction with the SL structure in RNA2. The N-terminal 50 aa of RCNMV CP are rich in lysine residues and are essential for virion formation.

RCNMV virions are stable in conditions in which divalent cations such as calcium and magnesium ions are abundant. In contrast, the virions are unstable when divalent cations are depleted. Low-divalent-cation environments such as those found within the cytoplasm of a cell might be favorable for uncoating the virion and exposing the genomic RNAs for gene expression. The unique response of RCNMV virions to changes in divalent cation concentrations has been exploited for the development of plant viral nanoparticles for controlled delivery of the anticancer drug doxorubicin. In addition to medical applications, a study has shown that RCNMV nanoparticles improve the performance of abamectin, a potent nematocide that targets a broad spectrum of plant parasitic nematodes, by enhancing the poor mobility of abamectin in soil.

Dianthoviruses multiply to high concentrations in infected plants and the virions are stable *in vitro*. The release of dianthoviruses from infected roots into surrounding environments such as soil and drainage water has been reported. However, it has not been determined whether soil-inhabiting organisms transmit dianthoviruses in the field. *Olpidium* spp., nematodes, and bees have been proposed as vectors of RCNMV, CRSV, and SCNMV, respectively.

Gene Expression

After entry into host cells, the genomic RNA of (+)RNA viruses recruits host ribosomes to act as a template for translation. Like all viruses in the family *Tombusviridae*, the genomic RNAs of dianthoviruses lack both a 5'-cap structure and a 3'-poly(A) tail.

Thus, to produce their encoded proteins efficiently, dianthoviruses use cellular translational machinery in a non-canonical, cap-independent mechanism. RCNMV uses different modes for cap-independent translation of its bipartite genomic RNAs.

The protein p27 is directly translated from RNA1 in a cap-independent manner. Two *cis*-acting RNA elements play essential roles in the translation of RNA1: a 3'-cap-independent translation enhancer termed 3'TE-DR1 and an adenine-rich sequence (ARS) in the 3'UTR. 3'TE-DR1 is essential for recruiting the eukaryotic initiation factors eIF4F/eIFiso4F and ribosomes to RNA1. ARS, located 60 nucleotides upstream from 3'TE-DR1, recruits a host poly(A)-binding protein (PABP) to RNA1 through a direct RNA-protein interaction. The ARS-PABP interaction mediates the recruitment of eIF4F/eIFiso4F to 3'TE-DR1. Although 3'TE-DR1 can bind to both eIF4F and eIFiso4F, RNA1 preferentially utilizes eIF4F for its translation. Because the cap-independent translation of RNA1 is scanning dependent, ribosomes should be recruited to the 5-end of the viral RNA. However, the mechanism by which the 3'UTR of RNA1 coordinates the recruitment of ribosomes to the 5'end remains elusive.

The protein p88^{pol} is translated via -1 programmed ribosomal frameshifting (-1PRF) from RNA1. Three *cis*-acting RNA elements required for -1PRF have been identified: a shifty heptanucleotide sequence GGAUUUUU where the reading frame shifts, a highly structured bulged SL immediately downstream from the slippage site, and a small stable SL structure located between ARS and 3'TE-DR1. Intramolecular base-pairing between the bulge of the second element and the loop sequence of the third element mediates efficient -1PRF of RCNMV RNA1. This long-distance RNA-RNA interaction is likely to be conserved in all dianthoviruses.

CP is translated from sub-genomic RNA (CPsgRNA). CPsgRNA is likely to be generated via a premature termination mechanism, where the viral replicase terminates internally during negative-strand RNA {(−)RNA} synthesis. The 3'-truncated (−)RNA is then used as a template for CPsgRNA synthesis. CPsgRNA transcription requires intermolecular base-pairing between RNA2 (TA element) and RNA1 (TA-binding site located immediately upstream of the transcription start site), which is likely to be important for premature termination of the viral replicase complex (VRC) during (−)RNA synthesis. CPsgRNA is identical to the 3'-terminal 1.5 kb of RNA1 and therefore possesses the same 3'TE-DR1, which is also essential for translation from CPsgRNA.

MP is translated from RNA2. Unlike RNA1, RNA2 lacks *cis*-acting RNA elements such as 3'TE-DR1 and ARS. Instead, cap-independent translation of RNA2 seems to be coupled with RNA2 replication. That is, only the RNA2 that is generated *de novo* through replication seems to act as a template for translation. Interestingly, RNA2 preferentially utilizes eIFiso4F rather than eIF4F. The *cis*-acting RNA elements that recruit eIFiso4F and/or ribosomes to RNA2 have not yet been identified. A translation-silencer element has been identified in the basal stem structure of the 5'UTR (5'BS) of RNA2, and translation-enhancer activity is found in the 5'UTR other than 5'BS. Therefore, the 5'UTR may coordinate cap-independent and replication-coupled translation of RNA2. The molecular mechanisms underlying replication-coupled translation of RNA2 remain elusive.

RNA Replication

Replication of RCNMV takes place at the cytoplasmic surface of the host endoplasmic reticulum (ER) membrane. At the early phase of replication, RCNMV replicates at punctate structures on cortical ER. Later, such punctate structures disappear, and instead, a large aggregated ER structure emerges at the perinuclear region. p27 plays a key role in the biogenesis of the viral replication compartments. An amphipathic α -helix of p27 is essential for targeting p27 to ER membranes and the assembly of the VRC (termed the 480 kDa replicase complex). The p27-p27 and the p27-p88^{pol} interactions are prerequisite for the assembly of the 480 kDa replicase complex. The C-terminal half of p27 is responsible for the p27-p27 and the p27-p88^{pol} interactions, whereas the nonoverlapping region of p88^{pol} is responsible for the p27-p88^{pol} interaction.

After translation in the cytoplasm, the genomic RNA of (+)RNA viruses must be recruited to the viral replication compartment and used as a template for (−)RNA synthesis. To distinguish viral genomic RNAs from host-derived RNAs, viral replication proteins must have mechanisms to specifically recognize viral RNAs as replication templates. *Cis*-acting RNA elements that are important for replication have been identified in the 3'UTR of both genome segments. In RNA1, two SLs, termed SLDE and SLF, and the intervening sequence are likely to act as the core promoter for (−)RNA synthesis. The corresponding *cis*-acting RNA elements are also present in RNA2. Interestingly, RNA2 has additional RNA elements that are also crucial for (−)RNA synthesis: 5'BS in the 5'UTR, a TA element in the coding region of MP, and a Y-shaped RNA element (YRE) in the 3'UTR. Because RNA2 utilizes a replication protein supplied from RNA1, these additional *cis*-acting RNA elements probably contribute to recruiting viral replication proteins. Indeed, YRE is an essential *cis*-acting RNA element that is recognized by the p27 replication protein. The p27-YRE interaction is required for the recruitment of RNA2 to the sites of viral replication. In contrast, RNA1 has no RNA element that interacts with p27 and/or p88^{pol} supplied in *trans*, and p88^{pol} is only able to act *in cis* on RNA1 during replication. This *cis*-preferential requirement for p88^{pol} in the replication of RNA1 may be explained by the finding that p88^{pol} appears to bind to the 3'UTR of RNA1 in a translation-coupled manner. The translation-coupled binding of p88^{pol} may enable rigorous template selection of RNA1 without special *cis*-acting elements such as YRE.

Host Factors in Dianthovirus RNA Replication

Accumulating evidence has suggested that interactions between viral proteins and host factors are important determinants of successful viral infection. Recent proteomics approaches followed by functional studies have suggested that RCNMV hijacks a number of host proteins for its robust replication.

Heat shock protein 70 (Hsp70) and Hsp90 are abundant and highly conserved molecular chaperones that play central roles in protein homeostasis, including the folding of newly synthesized proteins and the assembly of macromolecular protein complexes. Like many other (+)RNA viruses, RCNMV requires these molecular chaperones for replication. p27 binds to Hsp70 and Hsp90 *in vitro* and *in vivo*. Hsp70 regulates the assembly of the 480 kDa viral replicase complex by preventing its aggregation, while Hsp90 promotes the p27–YRE interaction. Thus, RCNMV utilizes Hsp70 and Hsp90 to regulate different steps in RNA replication before starting (–)RNA synthesis.

One of the hallmark features of eukaryotic (+)RNA virus replication is the establishment of viral replication compartments, which are generated *de novo* during virus infection via massive rearrangement of host membranes and lipid metabolism. A host small GTPase ADP ribosylation factor 1 (Arf1) is a central regulator of the biogenesis of the COPI vesicle that mediates Golgi-to-ER retrograde vesicle trafficking. Arf1 is critical for RCNMV replication. p27 directly interacts with and recruits Arf1 from the Golgi to the viral replication compartment; in fact, RCNMV seems to hijack Arf1 function to establish the viral replication compartment. Another important host factor for RCNMV replication is phospholipase D (PLD). PLD mediates the biogenesis of phosphatidic acid (PA) through hydrolysis of phosphatidylethanolamine or phosphatidylcholine. The interaction of p27 with PA was demonstrated by a protein–lipid overlay assay, and RCNMV was shown to induce an approximately threefold accumulation of PA in infected plant leaves. p88^{pol} interacts with and recruits PLD α and PLD β of *Nicotiana benthamiana* to the viral replication compartment during RCNMV replication. PLD-derived PA is required for RCNMV replication, and exogenously added PA was shown to stimulate RNA replication in protoplasts and (–)RNA synthesis in plant-derived cell-free extracts. Therefore, RCNMV is likely to induce enrichment of PA at the viral replication compartment via PLD to establish a suitable environment for viral RNA replication.

It is known that many plant viruses induce production of reactive oxygen species (ROS) during infection. ROS are often associated with host defense against biotrophic pathogens such as fungi and bacteria. However, the role of ROS in plant–virus interactions has been obscure. RCNMV strongly induces intracellular ROS production in infected cells. Respiratory burst oxidase homolog (RBOH) is one of the major host-plant enzymes responsible for the production of ROS in response to various types of stresses. Interestingly, RCNMV replication protein p27 interacts with the RBOHB of *N. benthamiana* and recruits it to the viral replication compartment. In addition, p27 is sufficient for induction of ROS production in an RBOH-dependent manner and gene silencing or pharmacological inhibition of RBOH activity compromises viral replication. These findings suggest that RCNMV hijacks a host ROS-generating enzyme to boost viral replication. RCNMV appears to activate RBOH to mediate virus-induced intracellular ROS production. A subgroup II calcium-dependent protein kinase (CDPKiso2) of *N. benthamiana* phosphorylates the N-terminal region of RBOHB and activates its enzyme activity. CDPKiso2 is required for p27-triggered ROS production and viral RNA replication. Although p27 can form a complex with CDPKiso2, this interaction seems to be indirect. Instead, a host scaffold protein, receptor for activated C kinase 1 (RACK1), bridges the interaction of p27 with CDPKiso2. Indeed, RACK1 is required for the p27–CDPKiso2 interaction, p27-mediated ROS production, and viral RNA replication. Together, these findings suggest that RCNMV co-opts RACK1 to integrate CDPKiso2 into the viral replication compartment to promote RBOH activation and ROS production.

Cell-to-Cell and Systemic Movement

A 35 kDa MP encoded by RNA2 is essential for the cell-to-cell and systemic movement of dianthoviruses. The amino acid sequences of the MPs of dianthoviruses suggest that they belong to the 30K superfamily. RCNMV MP has the ability to bind single-stranded nucleic acids cooperatively. However, unlike the MP of tobacco mosaic virus (TMV), which also belongs to the 30K superfamily, RCNMV MP does not unfold single-stranded RNA molecules *in vitro*. Despite having such different characteristics, the MPs of TMV and RCNMV are functionally homologous because RCNMV MP can support the systemic infection of a movement-deficient mutant of TMV in *N. benthamiana*. Although it has not been determined whether dianthoviruses move cell-to-cell as virions or as RNA–MP complexes, the former is unlikely because the CP is dispensable for the cell-to-cell movement of dianthoviruses in several host plants.

RCNMV MP localizes at plasmodesmata (PD) and increases their size exclusion limit. In addition, MP also localizes to small punctate structures at the cortical ER that contain the VRCs during the early phase of viral infection. Colocalization of MP to the cortical VRCs is associated with the replication of RNA1, but not that of RNA2, and is required for the cell-to-cell movement of RCNMV. Glyceraldehyde 3-phosphate dehydrogenase A is involved in this colocalization event and is required for the efficient cell-to-cell movement of RCNMV in *N. benthamiana*.

Although a CP-deficient mutant of RCNMV is able to systemically infect *N. benthamiana* at lower temperatures such as 17°C, virion formation is required but not sufficient for the systemic movement of dianthoviruses.

RNA Silencing Suppression

The importance of RNA silencing mediated by small RNAs in the defense of various organisms, including plants, against viruses has been well established. To counteract antiviral RNA silencing, most plant viruses encode at least one viral silencing suppressor protein (VSR). RCNMV has at least two strategies to counteract host RNA silencing. Suppression of RNA silencing by RCNMV

closely correlates with viral (–)RNA synthesis and accumulation of the 480 kDa replicase complex, implying that RCNMV interferes with host RNA silencing in an RNA replication-associated manner. RCNMV replication also inhibits microRNA biogenesis that is catalyzed by the host RNaseIII-like enzyme dicer-like 1 (DCL1). Higher viral accumulation was observed during RCNMV infection in a *dcl1* mutant *Arabidopsis*. However, the role of DCL1 or its homologs in suppression of RNA silencing during RCNMV replication remains unknown. In addition to replication-associated RNA-silencing suppression, it has been reported that RCNMV MP has VSR activity. The functional domains required for VSR activity in MP differ from those required for cell-to-cell movement.

This is an update of T. Fukuhara, H. Moriyama, Endornavirus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00580-X](https://doi.org/10.1016/B978-012374410-4.00580-X).

Glossary

Cytoplasmic male sterility Male sterility caused by a cytoplasmic factor.

Endophyte A bacterium or fungus that lives within a plant for at least part of its life cycle without causing any apparent disease.

Horizontal transmission The transmission of infections (e.g., viruses) between members of the same species.

in silico An expression meaning “performed on computer” in reference to biological experiments.

Isogenic line Genetically identical pure-breeding group of individuals.

Mycorrhiza A symbiotic association between a green plant and a fungus.

Mycovirus A virus that infects fungal species.

Oomycete A fungus-like eukaryotic microorganism that is a filamentous, microscopic, and absorptive organism.

Open reading frame The part of a reading frame that has the ability to be translated into a protein.

Phytopathogen An organism that is pathogenic to plants.

Polyprotein A protein (produced by viruses) that is cleaved to produce a number of functional proteins.

Positive-sense, single-stranded RNA virus A virus that uses positive sense, single-stranded RNA as its genome.

RNA silencing The mechanism of transcriptional and post-transcriptional gene silencing mediated by 21–24 nt small RNAs.

RNA-dependent RNA polymerase An enzyme that synthesizes RNA from an RNA template.

Vertical transmission The transmission of parasites (e.g., virus) or symbionts from parents to children.

Introduction

Viruses are thought to affect the phenotype of their hosts, and plants infected with viruses usually exhibit visible disease symptoms. Thus, infection of crop plants and vegetables with viruses severely damages their yield and quality. Therefore, commercially available crops, vegetables, and fruits are believed to be virus-free, but they are often asymptotically infected with persistent viruses. As these plants are infected with persistent viruses and exhibit no symptoms, they are sold commercially.

Double-stranded RNAs (dsRNAs) have frequently been detected from various healthy plants. These dsRNAs are not transcribed from the host genome DNAs, and replicate (propagate) independent of their host genome DNAs as bacterial plasmids do. These dsRNA replicons have common properties that differ from those of conventional RNA viruses: (1) Most of these dsRNAs have no obvious effect on the phenotype of their host plants; (2) they are distributed throughout all tissues of the host plants at a stable low concentration; (3) they are transmitted to the next generation only through the gametes; (4) their horizontal transfer to other plants has never been proven. The size of these dsRNAs varies from 1.5 to 20 kbp.

Smaller dsRNAs (about 2.0 kbp) are often found with virus-like particles, and some of these dsRNAs have been classified as viruses in the family *Partitiviridae*. Partitiviruses have two unrelated linear dsRNA segments, each about 2.0 kbp in size, which encode a viral RNA-dependent RNA polymerase (replicase, RdRp) and a capsid (coat) protein (CP). These partitiviruses are typical persistent viruses that asymptotically infect crop plants and vegetables.

Larger dsRNAs (more than 10 kbp) are probably not associated with distinct virus-like particles, because no virus-like particles have been isolated in preparations obtained with various purification procedures. Thus, these large dsRNAs were previously referred to as RNA plasmids, enigmatic dsRNAs or endogenous dsRNAs. However, now these large dsRNAs are also recognized as persistent viruses, and named endornaviruses in the genus *Alphaendornavirus* of the family *Endornaviridae*.

Acute virus infection severely damages the yield and quality of crop plants and vegetables, so phytopathologic studies aimed at protecting crop plants and vegetables from virus infections have been conducted, and many acute plant viruses have been extensively studied. In contrast, because persistent viruses asymptotically infect host plants, studies on persistent plant viruses have been more limited than those on acute plant viruses. A typical persistent RNA viruses, endornaviruses, are the focus of this article.

Plant Endornaviruses

Linear dsRNAs of approximately 14 kbp in length were often found in rice (*Oryza sativa*), barley (*Hordeum vulgare*), melon (*Cucumis melo*), and bell pepper (*Capsicum annuum*). These dsRNAs were not transcribed from their host DNA genomes. Furthermore they propagate independent of their host genomes but have several common properties that are different from those of conventional viruses. Complete nucleotide sequences of these dsRNAs isolated from broad bean (*Vicia faba*), cultivated rice (*O. sativa*) and wild rice

Fig. 1 Genome organizations of *Oryza sativa* endornavirus (OsEV), the type species of *Alphaendornavirus*, and *Sclerotinia sclerotiorum* endornavirus 1 (SsEV1), the type species of *Betaendornavirus*. The site-specific nick is only present in the coding strand of alphaendornaviruses.

(*O. rufipogon*) were reported about two decades ago. These dsRNAs encoded a single open reading frame (ORF) of approximately 4600 amino acid (aa) residues, in which the conserved viral RdRp and RNA helicase (Hel) domains were found (Fig. 1). Phylogenetic analyses of these two conserved domains indicated that these dsRNAs share a common ancestor with the alpha-like supergroup of positive-sense single-stranded RNA (ssRNA) viruses including many plant ssRNA viruses, such as Tobacco mosaic virus (TMV) and Cucumber mosaic virus (CMV). Consequently, the International Committee on Taxonomy of Viruses (ICTV) classified these dsRNAs as members of a new virus genus *Endornavirus* within a new virus family *Endornaviridae*, and named the three dsRNAs as *Vicia faba* endornavirus (VfEV), *Oryza sativa* endornavirus (OsEV) and *Oryza rufipogon* endornavirus (OrEV).

Deep-sequencing (RNA-seq) analyses have revealed asymptomatic infections of various viruses in crop plants and vegetables as well as wild plants. Some of these virus sequences have been recognized as members of the family *Endornaviridae*. To date, 14 endornaviruses have been found in plants, including barley, melon, bell and hot peppers (*C. annuum*), bottle gourd (*Lagenaria siceraria*), common bean (*Phaseolus vulgaris*), avocado (*Persea americana*) and others (Table 1).

The eighth and ninth reports of the ICTV classified the family *Endornaviridae* in the dsRNA virus group. However, an alternative opinion based on phylogenetic analyses claims that the family *Endornaviridae* should be classified in the positive-sense ssRNA virus group, and large dsRNAs of endornaviruses should be considered as their replication intermediates. Consequently, the tenth report of the ICTV, published recently, classifies the family *Endornaviridae* in the positive-sense ssRNA virus group.

Fungal Endornaviruses

A wide variety of viruses have been found in many fungi, including phytopathogenic and endophytic fungi and mushrooms. Fungal viruses are termed mycoviruses, and most mycoviruses contain dsRNAs as their genome. dsRNA mycoviruses are primarily classified into four families, *Partitiviridae*, *Totiviridae*, *Chrysoviridae*, and *Endornaviridae*, but novel mycoviruses recently discovered should be classified into a new genus and/or family. In general, mycoviruses persistently infect the host fungus and are transmitted vertically via host cell division, and infections are usually symptomless.

The violet root rot fungus, *Helicobasidium mompa*, occurs on various plants, and contains various sized dsRNAs. A large dsRNA (L1 dsRNA) in the V670 strain of *H. mompa* has been identified as a hypovirulence factor. The nucleotide sequence of this dsRNA encodes a single long ORF containing conserved RdRp and Hel domains exhibiting significant similarity to those encoded by plant endornaviruses described above, indicating that this dsRNA is a member of the family *Endornaviridae*. The virus was subsequently named *Helicobasidium mompa* endornavirus 1 (HmEV1). An increasing number of recent reports have described nucleotide sequences that likely belong to viruses of the family *Endornaviridae*, especially from plant pathogenic fungi.

Currently, the family *Endornaviridae* consists of two genera, *Alphaendornavirus* and *Betaendornavirus*, which are classified based on genome size and the presence of unique protein domains. Seven fungal endornaviruses, which have shorter genomes (< 12.6 kbp) than alphaendornaviruses and lack the UDP (uridine diphosphate) glucosyltransferase (UGT) domain present in the majority of alphaendornaviruses, have been classified as members of the genus *Betaendornavirus* (Fig. 1). To date, the genus *Alphaendornavirus* includes 20 viruses that infect plants, fungi, and oomycetes, whereas the genus *Betaendornavirus* includes seven viruses that infect ascomycete fungi (Table 1, Fig. 2).

Eight novel endornavirus-like sequences were recently identified from isolates of mycorrhizal (*Ceratobasidium*) fungi isolated from pelotons within root cortical cells of wild indigenous orchid species in Western Australia. The partial and complete sequences of viral RdRps shared low (9%–30%) identities with one another and with those of endornavirus RdRp described previously. Four putative viruses had longer genomes (> 20 kbp) than those of endornaviruses, and three had two ORFs within their genomes.

Table 1 List of species in the family Endornaviridae

Host type	Host species	Species name	Abbreviation
<i>Alphaendornavirus</i>			
Plant	Malabar spinach	<i>Basella alba endornavirus 1</i>	BaEV1
	Bell pepper	<i>Bell pepper endornavirus</i>	BPEV
	Melon	<i>Cucumis melo endornavirus</i>	CmEV
	Barley	<i>Hordeum vulgare endornavirus</i>	HvEV
	Hot pepper	<i>Hot pepper endornavirus</i>	HPEV
	Bottle gourd	<i>Lagenaria siceraria endornavirus</i>	LsEV
	Wild rice (W1714)	<i>Oryza rufipogon endornavirus</i>	OrEV
	Cultivated rice	<i>Oryza sativa endornavirus</i> ^a	OsEV
	Avocado	<i>Persea americana endornavirus 1</i>	PaEV1
	Common bean	<i>Phaseolus vulgaris endornavirus 1</i>	PvEV1
	Common bean	<i>Phaseolus vulgaris endornavirus 2</i>	PvEV2
	Common bean	<i>Phaseolus vulgaris endornavirus 3</i>	PvEV3
	Broad bean (447)	<i>Vicia faba endornavirus</i>	VfEV
	Winged bean	<i>Winged bean endornavirus</i>	WBEV1
	Mate	<i>Yerba mate endornavirus</i>	YmEV
Fungus	Powdery mildew fungus	<i>Erysiphe cichoracearum endornavirus</i>	EcEV
	Endophyte	<i>Grapevine endophyte endornavirus</i>	GEEV
	White root rot fungus	<i>Helicobasidium mompa endornavirus 1</i>	HmEV1
	Rhizoctonia	<i>Rhizoctonia cerealis endornavirus 1</i>	RcEV1
Protista	Phytophthora	<i>Phytophthora endornavirus 1</i>	PEV1
<i>Betaendornavirus</i>			
Fungus	Alternaria	<i>Alternaria brassicola endornavirus 1</i>	AbEV1
	Gray mold fungus	<i>Botrytis cinerea endornavirus 1</i>	BcEV1
	Gremmeniella	<i>Gremmeniella abietina endornavirus 1</i>	GaEV1
	Soil-borne fungus	<i>Rosellinia necatrix endornavirus 1</i>	RnEV1
	Sclerotinia blight fungus	<i>Sclerotinia minor endornavirus 1</i>	SmEV1
	White mold fungus	<i>Sclerotinia sclerotiorum endornavirus 1</i> ^a	SsEV1
	Truffle	<i>Tuber aestivum endornavirus</i>	TaEV

^aThe type species.

These two features of novel endorna-like viruses are unlike endornaviruses currently described, and they may challenge current taxonomic criteria for membership of the family Endornaviridae.

Endornaviruses From Other Eukaryotic Kingdoms

Plant pathogens of the genus *Phytophthora* have many of the same biological properties as fungi. However, on the basis of sequence similarities, plant pathogens of the genus *Phytophthora*, an oomycete, have been classified together with diatoms and brown algae into a protist group known as the Stramenopiles. Sequencing and phylogenetic analyses of a large dsRNA from a *Phytophthora* isolate from Douglas fir (*Pseudotsuga menziesii*) revealed that it encodes a single long ORF similar to those encoded by known plant and fungal endornaviruses. This was recognized as a member of the genus *Alphaendornavirus* and named *Phytophthora endornavirus 1* (PEV1).

Using an *in silico* bioinformatics approach to obtain full or partial cDNA sequences of genes and comparing them against known viral sequences in the NCBI (National Center for Biotechnology Information) Expressed Sequence Tag database, 119 novel virus-like sequences related to members of the families Partitiviridae, Totiviridae, Chrysoviridae, and Endornaviridae, were discovered. Among them one endornavirus-like sequence that exhibited significant similarity to the fungal endornavirus HmEV1 was identified from the sea louse (*Caligus rogercresseyi*). As the sea louse is a member of the phylum Arthropoda, this finding suggests that endornaviruses are also found in the animal kingdom.

Genome Organization

A recent ICTV report claimed, based on phylogenetic analyses, that endornaviruses are classified in the positive-sense ssRNA virus group, and that large dsRNAs should be recognized as their replication intermediates. However, ssRNA genomes of endornaviruses have never been isolated. Consequently, all cDNA cloning experiments were performed by using purified dsRNAs of

Fig. 2 Phylogenetic tree of selected endornaviruses, as modified from a tree constructed by Valverde *et al.* using the aa sequences of RdRp domains of endornaviruses. Abbreviations of virus names are indicated in Table 1. Reproduced from Valverde, R.A., Khalifa, M.E., Okada, R., *et al.*, 2019. ICTV virus taxonomy profile: Endornaviridae. Journal of General Virology 100 (8), 1204–1205.

endornaviruses as templates for cDNA synthesis. In this case, most endornavirus sequences were obtained from nucleotide sequences of cDNA clones. Recently, nucleotide sequences of endornaviruses have been obtained more easily from RNA-seq data of endornavirus-infected organisms.

The endornavirus genomes sequenced to date range from 9639 to 17,635 bp in length, and electron microscopic observations revealed that the dsRNAs of endornaviruses are linear (Fig. 3). They commonly encode a single ORF of 3148 to 5821 aa residues, and this long ORF is one of the unique molecular features of endornaviruses (Fig. 1). Conserved Hel and RdRp domains located in the central and C-terminal regions, respectively, of the long ORF are common features of all endornaviruses described to date (Fig. 1). Other conserved domains found in some, but not all, endornaviruses are viral methyltransferase (MTR), UGT, capsular polysaccharide synthetase (CPS), and cysteine-rich region (CRR) (Fig. 1).

Four plant endornaviruses [OsEV, OrEV, VfeEV and Bell pepper endornavirus (BPEV)], one fungal endornavirus (HmEV1), and one oomycete endornavirus (PEV1) belonging to the genus *Alphaendornavirus* were shown to contain a site-specific nick in the 5' region of the coding strand, which divides not only the coding strand but also the single long ORF (Fig. 1), but the nick has never been found in betaendornaviruses. The biological implications of this nick in the coding strand and the mechanism by which it is generated are unknown. However, because the divided coding strand can no longer be used as a template for non-coding strand synthesis (replication) or mRNA for translation of the protein, the nick must affect at least two important steps in the life cycle of endornaviruses. Therefore, endornavirus dsRNAs containing the nick may be remains (dead virus bodies) because they have a defect in translation and replication, even though these unique dsRNA molecules predominantly accumulate in the hosts infected by some alphaendornaviruses described above. The continuous ssRNA of the coding strand may play a vital role in the virus life cycle, but

Fig. 3 Electron micrograph of dsRNA molecules of *Oryza sativa* endornavirus (OsEV). Bar represents 1 μm . Figure reproduced with permission from Fukuhara, T., Moriyama, H., Pak, J.K., Hyakutake, T., Nitta, T., 1993. Enigmatic double-stranded RNA in Japonica rice. *Plant Molecular Biology* 21, 1121–1130.

there are no reports describing the isolation of ssRNA molecules of endonaviruses. These two molecular features – the single long ORF and the site-specific nick – have not been reported in other known RNA viruses.

Gene Products

All endonaviruses reported to date encode a single long ORF of approximately 3100 to 5800 aa residues, in which several conserved protein domains are found. This suggests that this long ORF encodes a polyprotein that is cleaved to produce a number of functional proteins. Indeed, potyviruses, which have a single long ORF of approximately 3000 aa residues, encode a single polyprotein consisting of eight functional proteins (see Potato Virus Y, Potyvirus). Therefore, endonaviruses likely encode a polyprotein containing more than 10 functional proteins. Indeed, several conserved protein domains have been found in all endonaviruses (Fig. 1), as discussed below. However, these putative proteins have never been experimentally detected by a specific antibody using a technique such as Western blot.

Conserved motifs encoding RdRp and Hel are found in the same regions of long ORFs encoded by most endonaviruses (Fig. 1), and these two proteins are structurally similar to those encoded by ssRNA viruses such as CMV and TMV. Thus, these putative RdRp and Hel probably function in the replication of the genome RNA, as their homologues encoded by ssRNA viruses are essential for the replication of their genomes. MTR (a capping enzyme for viral genomic RNAs) also probably functions in the replication of endonaviruses, similar to their homologues encoded by ssRNA viruses, but the conserved MTR motif is not found in some endonaviruses.

The enzyme UGT is commonly found in eukaryotes. This enzyme catalyzes the addition of the glycosyl group from a UDP-sugar to a small hydrophobic molecule. UGTs have been identified in dsDNA viruses, including baculoviruses and nucleopolyhedroviruses from insects. In insect cells, the viral ecdysteroid UDP-glycosyltransferase inactivates the molting hormones (ecdysteroids) of the host insect by sugar conjugation. Although a UGT gene has never been found in the genomes of the alpha-like supergroup of ssRNA viruses, it was found in strains of two hypoviruses (fungal ssRNA viruses), *Cryphonectria hypovirus 3* and *4* (CHV3 and CHV4). A conserved motif significantly similar to that of UGT was found in some alphaendonaviruses (Fig. 1). A conserved motif similar to that of CPS is also found in some endonaviruses (Fig. 1). However, the functions of both putative UGT and CPS proteins in endonaviruses remain unknown.

The ORF of endonaviruses is very large (Fig. 1), so it likely encodes several other proteins in addition to those already discussed. The ORF must encode a polyprotein, so it must also encode one or more proteinases to cleave the putative polyprotein into functional units such as RdRp, Hel, MTR, UGT and CPS. A similar situation is well known in potyviruses, which encode a polyprotein of approximately 3000 aa residues containing two proteinases (see Potato Virus Y, Potyvirus). The conserved CRR located in the N-terminal half of endornavirus ORFs may function as a proteinase (Fig. 1), because many proteinases (also known as cysteine proteinases) containing a conserved cysteine residue in their catalytic domain have been reported so far.

CP and movement proteins (MP) are essential for conventional plant viruses such as TMV and CMV. CP is essential for viral horizontal transmission from one host plant to another, and MP is essential for the movement of viruses from one cell to surrounding (neighboring) cells and systemic infection in host plants. Systemic propagation (infection) within the host plant mediated by MP and horizontal transmission (infection) from one host to other hosts mediated by CP constitute a fundamental propagation strategy for acute plant viruses. In contrast, endonaviruses have a symbiotic relationship with the host plant. Therefore, both CP and MP are probably not necessary for persistent propagation of endonaviruses.

Replication (RdRp Activity)

A limited number of reports have demonstrated the functions (or enzymatic activities) of proteins encoded by endonaviruses. The RdRp activity of endonaviruses was initially reported from a study of VfEV in the “447” line of broad bean (*V. faba*).

Purified cytoplasmic membranous vesicles containing VfEV had RdRp activity, which required Mg^{2+} ions and the four nucleotide triphosphates, and was unaffected by inhibitors of cellular DNA-dependent RNA polymerases such as alpha-amanitin and actinomycin D. RdRp activity was also detected in the crude microsomal fraction of OsEV-harboring rice cells. Like the VfEV RdRp activity, this RdRp activity was also highest in the presence of all four nucleotide triphosphates and Mg^{2+} ions, and was resistant to inhibitors of DNA-dependent RNA polymerases. Treatment of the purified microsomal fraction with proteinase K plus deoxycholate suggested that the RdRp enzyme complex is located in vesicles. So far, RdRp activity has been found only in two endornavirus-harboring plants mentioned above. Therefore, the available data concerning endornavirus replication are limited. There is a need to identify and characterize the endornavirus- and/or host-encoded proteins that are involved in endornavirus replication.

Vertical Transmission

Although horizontal transmission of endornaviruses has never been reported in plants, these viruses are frequently found in a variety of plants. For example, OsEV and BPEV are commonly detected in many cultivars of *japonica* rice and bell pepper, respectively. To understand why OsEV is widely distributed in *japonica* rice cultivars, crossing experiments with OsEV-harboring and OsEV-free plants were carried out to examine the efficiency of vertical transmission of OsEV. OsEV-harboring and OsEV-free plants were found to coexist in the *japonica* rice cultivar Nipponbare, and these two isogenic lines could not be distinguished on the basis of their appearance. The results of crossing experiments indicated that the efficiency of OsEV transmission via pollen was more than 98%, and that of transmission via ovules was 100%. Consequently endornaviruses are efficiently transmitted to progeny plants via both pollen and ovules, though differential centrifugation and sucrose density-gradient centrifugation experiments revealed that OsEV localizes in the cytoplasm of host cells. The high efficiency of OsEV transmission via both pollen and ovules is likely responsible for the wide distribution of OsEV in many rice cultivars. Analyses of the F2 progeny plants of cv. Nipponbare indicated that the absence of OsEV was not associated with any particular gene(s) in the OsEV-free plants. The observed inheritance of OsEV was different from that of other cytoplasmic genetic elements (e.g., chloroplasts and mitochondria), which are usually inherited only via egg cells.

OsEV has been found in many cultivars of *japonica* rice but not in any cultivars of *indica* rice (a subspecies of *O. sativa*). *Japonica* and *indica* are distinguishable on the basis of their phenotype (e.g., grain shape) and genotype (e.g., the distribution of transposons in their genomes). To determine the reason why OsEV is not found in *indica* rice cultivars, reciprocal crosses between an OsEV-harboring *japonica* variety (cv. Nipponbare) and an OsEV-free *indica* variety (cv. IR26 or Kasalath) were performed. When cvs. IR26 and Nipponbare were used, efficient transmission of OsEV via ovule (93%) and pollen (89%) was observed. However, when cvs. Kasalath and Nipponbare were used, OsEV transmission efficiency to F1 progeny was 68% via ovule and 20% via pollen, and transmission to F2 progeny plants also followed a complicated, non-Mendelian inheritance pattern. These results suggest that OsEV is unstable in *indica* rice plants, which may lack one or more genes that are involved in the maintenance (replication) of OsEV.

Similar crossing experiments with endornavirus-harboring bell-pepper plants (cv. Yolo Wonder) and endornavirus-free plants (cv. Jalapeño M or Hungarian Wax) demonstrated that BPEV is also inherited maternally and paternally to the next generation. Thus, the propagation of OsEV and BPEV (and probably other plant endornaviruses as well) may depend on seed-mediated transmission, and endornaviruses may survive in cooperation with their host plants. No horizontal spread of plant endornaviruses has been observed in the field, and no potential vectors have been identified.

Horizontal Transmission

In general, fungal endornaviruses as well as other mycoviruses persistently infect the host fungus, and are transmitted vertically via host cell division. Recently, however, it has been reported that natural infections of a phytopathogenic soil-borne fungus, *Rosellinia necatrix*, with a novel endornavirus, *Rosellinia necatrix endornavirus 1* (RnEV1), can occur under experimental soil conditions. Furthermore, it has also been demonstrated that *Sclerotinia minor* endornavirus 1 (SmEV1), which is found in a phytopathogenic fungus *Sclerotinia minor*, was readily transmitted horizontally via hyphal contact to isolates of different vegetative compatibility groups of *S. minor*, and transmitted vertically as well. Therefore, some fungal endornaviruses are able to transmit horizontally as well as vertically.

Regulation of Copy Number

All plant endornaviruses reported so far are likely to be found in all tissues of host plants at a stable low concentration, suggesting that their propagation strategy is probably different from that of acute ssRNA viruses. However, studies on the copy number of endornaviruses are limited. OsEV in rice plants is the only report that studied the regulation of copy number of endornaviruses. A comparison of the relative amount of OsEV with genomic DNA in host rice plants of cv. Nipponbare showed that OsEV is maintained at approximately 100 copies per cell. No significant difference in OsEV concentration was found in seedlings, roots,

and mature leaves, indicating that a mechanism to regulate copy number may exist in host rice cells. In contrast, the copy number of OsEV in cultured rice cells was found to be about 10-fold higher than in the cells of seedlings. Although no changes in the copy number of OsEV was found in suspension cultures over the course of three years, copy number returned to the original low level in rice plants regenerated from cultured cells. Furthermore, the copy number of OsEV in pollen grains was found to be 50-fold higher than in seedlings.

The steady replication of plant endornaviruses before every host cell division (both mitosis and meiosis) and their efficient transmission to the next generation via ovules and pollen are essential for endornavirus propagation because horizontal transmission likely does not occur. The unregulated increase of endornavirus replication could cause disease or lead to the death of host plants, as occurs with acute virus infections. Conversely, a decrease in copy number could cause the virus to disappear from the host plant (germ cells). The mating of host plants provides an opportunity for endornavirus propagation, so an increase in copy number only in pollen grains is a reasonable strategy to ensure virus transmission, despite their cytoplasmic localization. Unlike almost all other viruses, endornaviruses are not able to transmit horizontally, but they are capable of vertical transmission.

Pathogenesis

Endornavirus-harboring crop plants and vegetables are commercially available, indicating that these plants are healthy and common cultivars. Current data also indicate that most endornaviruses found in plants, with the exception of VfEV, cause asymptomatic and persistent infections in the host plant. For instance, BPEV and OsEV have been frequently found in commercially available bell pepper fruits and rice grains, respectively. Consequently we usually consume these fruits and grains that contain endornaviruses.

In the model cultivar of cultivated rice, Nipponbare, molecular biological analyses identified OsEV-harboring and OsEV-free plants. However, these two isogenic lines did not exhibit distinguishable phenotypes, and even rice breeders and farmers were unable to distinguish them. If the OsEV-harboring line had a lower harvest yield than the OsEV-free line, breeders and/or farmers would recognize this phenotype and discard the lower-yielding line.

In commercial cultivars of bell pepper grown in the United States, an endornavirus was found at a prevalence rate of 100%. The overall appearance of the two bell pepper near-isogenic lines, BPEV-harboring and -free, was similar. However, the BPEV-free line had a significantly higher percentage of seed germination than the BPEV-harboring line. Plant height, number of fruits, and total fruit weight in plants of the BPEV-free line were higher than in plants of the BPEV-harboring line, but these differences were not statistically significant. Other characteristics between the two lines, such as, stem diameter, percentage of dry weight, fruit volume, chlorophyll, carotenoid, and anthocyanin content, were similar. These results suggest that BPEV appears to have a weak parasitic relationship with the host.

Recently, variations in physiological traits have been reported in eight lines of common bean (*P. vulgaris*) cv. Black Turtle Soup, four of which were double-infected with *Phaseolus vulgaris* endornavirus 1 (PvEV1) and 2 (PvEV2), and four of which were endornavirus-free. Plants from all eight lines were morphologically similar and did not show statistically significant differences in plant height, wet weight, number of days to flowering and pod formation, pods per plant, pod thickness, seed size, number of seeds per pod, and anthocyanin content. However, the endornavirus-infected lines had faster seed germination, longer radicles, lower chlorophyll content, higher carotene content, longer pods, and higher weight of 100 seeds, all of which were statistically significant.

Over four decades ago, a cytoplasmic male sterility (CMS) trait in the “447” line of broad bean (*V. faba*) and cytoplasmic spherical bodies (CSBs) found in the cytoplasm of 447 plants were reported. These CSBs contained a large dsRNA of approximately 17.6 kbp in length, and a correlation between the CMS trait and the presence of a CSB with a large dsRNA in the “447” strain was reported. This dsRNA was the genome of VfEV, which is the only plant endornavirus that affects the visible phenotype of the host.

In general, mycoviruses asymptotically infect host fungi. However, HmEV1, which was first reported as a fungal endornavirus, was identified as the hypovirulence factor from the strain V670 of the violet root rot fungus, *Helicobasidium mompa*. Recently, the endornavirus, SmEV1, was isolated from the hypovirulent strain LC22 of *S. minor*, and hypovirulence and associated traits of strain LC22 and SmEV1 were readily co-transmitted horizontally via hyphal contact to isolates of different vegetative compatibility groups of *S. minor*. Therefore, SmEV1 is also a hypovirulence-associated mycovirus with a wide spectrum of transmissibility and has the potential for biological control (virocontrol) of diseases caused by *S. minor*.

Therefore, most endornaviruses asymptotically infect their hosts. However, in combinations between specific endornaviruses and their hosts, endornaviruses are pathogenic to hosts and their infection affects the host phenotype.

Virus-Host Relationship (Host RNA Silencing Against Endornaviruses)

RNA silencing (RNA interference) is the process of sequence-specific post-transcriptional gene silencing triggered by dsRNAs. Most eukaryotes, such as fungi, insects, and plants, sense exogenous long dsRNAs, such as viruses, because replication intermediates of ssRNA viruses are long dsRNAs. They then activate the RNA silencing pathway for defense against virus infection. Extensive studies on the interactions between acute ssRNA viruses and host plants such as *Arabidopsis thaliana* revealed that RNA silencing functions as an innate defense system against virus infections in plants. In the RNA silencing pathway, a Dicer or Dicer-like (DCL) endoribonuclease cleaves long viral dsRNAs into viral small interfering RNAs (vsiRNAs), which then associate with an Argonaute

(AGO) protein. The vsiRNA-loaded AGO proteins then slice the viral genomic ssRNAs. However, many acute ssRNA viruses encode one or several viral suppressors of RNA silencing (VSR), which inhibits the host RNA silencing system, thus enabling the virus to overcome the host defense system and propagate systemically in the host plant.

Plant endornaviruses are likely maintained within the host plant for hundreds of generations, suggesting that the host plant regulates virus propagation and that some host factors control virus replication so that it is coordinated with host cell division. If host plants did not have such factors (proteins), those harboring endornaviruses would exhibit disease symptoms presumably due to unregulated virus propagation, or some of the plant's somatic or germ cells would lose endornaviruses. Therefore, host plants likely express factors that control endornaviruses as symbiont-like parasites. Candidate host factors for regulating endornaviruses could be proteins that constitute the RNA silencing machinery. Indeed endornavirus-derived vsiRNAs have been detected in host plants infected with OsEV, BPEV, PvEV1 and PvEV2, indicating that the host RNA silencing machinery recognizes endornaviral dsRNAs.

The copy number and inheritance of OsEV were examined in transgenic rice plants with a knock-down (KD) construct of genes for the RNA silencing machinery, *OsDCLs* or host RNA-dependent RNA polymerases. A low vertical transmission rate and the disappearance of OsEV during somatic cell divisions were observed in some *OsDCL2*-KD plants, suggesting that KD of a Dicer gene negatively affects the maintenance of OsEV in host plants. The host RNA silencing system may be necessary for persistent infection by endornaviruses because it provides stringent regulation of low copy number and efficient vertical transmission to the next generation. RNA silencing functions as a defense against acute virus infection, but it may also function as a host factor that maintains persistent infections of endornaviruses by keeping their copy number low.

Nomenclature

aa	Amino acid(s)	MP	Movement protein
AAP	Acquisition access period	NGS	Next generation sequencing
CP	Coat protein	nt	Nucleotide(s)
DMB	Double-membraned body	ORF	Open reading frame
ELISA	Enzyme-linked immunosorbent assay	PCR	Polymerase chain reaction
ER	Endoplasmic reticulum	RdRP	RNA-dependent RNA polymerase
GP	Glycoprotein precursor	RNP	RNA ribonucleoprotein
HPD	High Plains disease	RRD	Rose rosette disease
kb	Kilobase	RT-PCR	Reverse transcription polymerase chain reaction
kDa	Kilo Dalton	ssRNA	Single-stranded RNA
		UTR	Untranslated terminal regions

Glossary

Double-membraned bodies Double-membraned proteinaceous structures enveloping the virus particles.

Introduction

Although they were associated with typical symptoms on their hosts, *i.e.*, chlorotic ringspot and mosaic (**Fig. 1**), the nature and identity of fimoviruses remained unknown for a long time. This was mainly due to the difficulty of isolating the fimoviruses by mechanical transmission onto herbaceous hosts and to the abnormal conformation of virus particles observed under the electron microscope, since their proteinaceous structures, known as double-membraned bodies (DMBs), was different from all other plant viruses known at the time.

Today, the family *Fimoviridae*, order *Bunyavirales*, includes only one genus (*Emaravirus*), which comprises nine species: *European mountain ash ringspot-associated emaravirus* (as a type species), *Actinidia chlorotic ringspot-associated emaravirus*, *Fig mosaic emaravirus*, *Pigeonpea sterility mosaic emaravirus 1*, *Pigeonpea sterility mosaic emaravirus 2*, *Redbud yellow ringspot-associated emaravirus*, *Raspberry leaf blotch emaravirus*, *Rose rosette emaravirus* and *High Plains wheat mosaic emaravirus*. It also includes several tentative emaravirus species: *Actinidia emaravirus 2* (AcEV-2), *Blackberry leaf mottle-associated virus* (BLMaV), *Camellia japonica associated emaravirus 1* (CjEV-1), *Camellia japonica associated emaravirus 2* (CjEV-2), *Jujube yellow mottle-associated virus* (JYMaV), *Lilac chlorotic ringspot-associated virus* (LiCRaV), *Palo verde broom virus* (PVBV), *Pistacia virus B* (PiVB), *Ti ringspot-associated virus* (TiRSaV), *Perilla mosaic virus* (PerMV) and *Woolly burdock yellow vein virus* (WBYVV).

All these viruses are characterized by a multipartite negative-sense ssRNA genome composed of four to eight segments (nine, in the case CjEV-1) contained within spherical virions. Most of these viruses are vectored in nature by eriophyid mites, which are known to have a highly specific relationship with their plant hosts, thus explaining the rather restricted host range that characterize them.

Classification

Fimoviruses are distantly related to orthospoviruses and orthobunyaviruses of the families *Tospoviridae* and *Peribunyaviridae*, respectively. They share with them the following common features: (1) a multipartite, negative-sense, ssRNA genome, which in the case of fimoviruses consists of four to eight segments; (2) a high sequence identity with orthologous proteins of members of the order *Bunyavirales* at equivalent genome positions in the first three RNAs (corresponding to L, M and S RNA segments); (3) the presence of five conserved motifs (A-E) in the amino acid sequence of their RNA-dependent RNA Polymerase (RdRP), similar to those in the L segment-encoded protein of members of the order *Bunyavirales*; (4) the virus particles are typically enveloped in membranes; (5) the presence of conserved nucleotide sequences at both the 5'- and 3'-termini of all genomic RNAs segments of fimoviruses, but not identical to those of other members of the order *Bunyavirales*.

Virion Structure

Fimoviruses are approximately spherical and enveloped virions with a diameter of 60–200 nm (**Fig. 2**). DMBs have an envelope consisting of a unit membrane approximately 12 nm thick, which is apparently acquired from the endoplasmic reticulum, containing proteinaceous

Fig. 1 Host symptoms caused by emaraviruses: FMV-infected plants showing chlorotic ringspots on leaves (a) and fruits (c), together with mosaic-like symptoms, *i.e.*, vein clearing and leaf mottling (b). FMV-infected cyclamen plants showing flower discoloration (d), mosaic (e) and leaf deformation (f). PPSMV-1-infected plants showing ringspot (g), chlorosis and mosaic (h), yellowing and sterility of flowers (i). EMARaV-infected plants showing ringspots (j), mottling (k) and mosaic (l) symptoms.

Fig. 2 Groups of double-membraned bodies (DMB) in the cytoplasm of cells from a fig seedling infected with FMV. Arrows point to the aggregates of convoluted electron-dense filamentous elements (DMBs). Bar = 200 nm.

material and fine fibrils. In ultrathin sections they are frequently found in association with amorphous electron-dense material. DMBs are present in all cell types except those of the vascular bundles and are rarely observed in bundle sheath parenchyma cells.

Genome

The virus genome comprises from four to eight segments of negative sense ssRNA ([Table 1](#)). Genomic RNAs are not capped or polyadenylated and all contain complementary sequences (13–20 nt, depending on the RNA segment) at their 5′- and 3′-termini conserved in all viral genomic RNA components. The lengths of 5′ and 3′ untranslated terminal regions (UTR) of each viral segment are very variable in the different species, ranging from 40 to 50 nt up to 600–700 nt in length. All emaraviruses have a similar genomic organization, and each RNA is composed of a single ORF in negative polarity ([Fig. 3](#)).

- (1) RNA-1 is 6981–7217 nt long and contains ORF1 that encodes a RdRP of a predicted molecular mass of 265–272 kDa (P1). In a delimited area of this ORF there are the five motifs also conserved in all bunyavirids, which correspond to the core polymerase module of the RdRP active site.
- (2) RNA-2 is 2054–2399 nt long and contains ORF2, encoding a glycoprotein precursor (GP) with a predicted molecular mass of 73–83 kDa (P2). P2 shares several conserved motifs, including one predicted cleavage site that may generate two larger glycoproteins, Gn (20–23 kDa) and Gc (52–53 kDa). A third smaller glycoprotein (Gs), consisting of 23 aa (2.6 kDa), has been predicted in the case of Actinidia chlorotic ringspot-associated virus (AcCRaV).
- (3) RNA-3 is 1220–1678 nt long and contains ORF3, encoding a nucleocapsid protein (NP) of 32–35 kDa (P3). In the case of High Plains wheat mosaic virus (HPWMoV), two RNA-3 consensus sequences encoding the NP were found, with 12.5% sequence divergence. This protein contains stretches of positively charged aa (BindN specificity, 80%) that are probably involved in RNA binding.
- (4) RNA-4 is 1342–1675 nt long (1154 nt in CjEV-2) and contains ORF4, encoding a putative movement protein (MP) of 38–43.6 kDa (P4), having structural elements resembling the consensus secondary structure of the 30K superfamily of plant virus MPs. In the case of European mountain ash ringspot-associated virus (EMARaV), the MP is encoded by the RNA-5 (# LR536382) and not by RNA-4 (# NC_013108).

More uncertainty surrounds the exact number and functionality of the other genomic RNAs that complete the emaravirus genome. Unlike the first four RNAs examined so far, the sequence homologies and the lengths of orthologs RNA-5 to RNA-8 in the different emaraviruses are much less significant. A ninth RNA (RNA-9) has been to date detected in the only CjEV-1. An exception is the high sequence identity (93%) shown in the RNA-6 of Pigeonpea sterility mosaic viruses 1 and 2 (PPSMV-1 and PPSMV-2), thus suggesting that the RNA-6 encoded protein is performing a conserved function in virus biology for both PPSMV-1 and 2. Instead of one ORF in all genomic RNAs of emaraviruses, unexpectedly, only RNA-6 of RRV has shown the presence of two different ORFs (7.4 kDa and 27.1 kDa).

Studies on the genetic variability within the population of different emaraviruses [Fig mosaic virus (FMV), Raspberry leaf blotch virus (RLBV), HPWMoV, Redbud yellow ringspot-associated virus (RYRSaV), PPSMV-1 and PPSMV-2] have shown significant differences in nucleotide sequences among isolates of different origins, which in the case of RNA-3 (NP) never exceeded 15%. This variability was generally lower than that found in RNA-1 and RNA-2 of FMV, whereas RNA-4 (MP) was more conserved than RNA-3 in the case of PPSMV-1 and PPSMV-2.

Table 1 List of members and tentative members of the Genus *Emaravirus* in the family *Fimoviridae*. Name, Acronym and Accession # of each genomic RNA is provided

Species names virus names	Acronym	Accession #

^aThe former RNA-4 of EMARaV reported in the GenBank is here reported as RNA-5 and *vice versa*.^bAn additional RNA segment (RNA 9, Accession #. MN557028) has been identified.^cNo sequences are available in GenBank.^dOnly the sequence of a partial RNA segment is available in GenBank.

Fig. 3 Schematic representation of the organization of the six RNA segments constituting the genome of European mountain ash ringspot-associated virus (EMARaV); the type species of the genus *Emaravirus*. Expression products of each RNA (p1 to p6) are represented as dark gray boxes. The function and estimated molecular weight of each protein are reported below boxes. Arrows represent the virion-complementary sense RNA, from which the proteins are translated. Figure not drawn to scale.

In addition, interspecies recombination events were detected among PPSMV-1 and PPSMV-2 segments, two species commonly found in mixed infections in pigeonpea plants. Similar RNA segment reassortments were reported for FMV and BLMaV.

The phylogenetic trees inferred from the sequences of structural proteins (P1 to P4) of emaraviruses and putative emaraviruses in general displayed two clades (Fig. 4). The first group includes AcCRaV, AcEV-2, BLMaV, EMARaV, FMV, PiVB, PPSMV-1, PPSMV-2, RRV and RYRSaV, whereas the second group comprises HPWMoV, RLBV, PVBV, CjEV-1, CjEV-2, TiRSaV and JYMaV, among which the genomes of RLBV, HPWMoV and CjEV-1 have been reported to contain eight genomic RNA segments.

Life Cycle (Replication)

Like other negative sense ssRNA multipartite viruses, some fimoviruses are known to use “cap snatching” to initiate transcription and facilitate translation of their mRNAs, since, unlike the polymerases from non-segmented negative strand RNA viruses, they do not possess a capping activity. Cap-snatching involves binding of host capped mRNAs to the ribonucleoproteins (RNPs), cleavage of these RNAs close to the 5' cap by a viral endonuclease activity and use of the short-capped fragments as primers for viral mRNA transcription. As for other bunyavirids, the replication of fimoviruses probably occurs in the cytoplasm.

Epidemiology

Transmissibility by eriophyid mites is one of the most significant features shared by the different emaraviruses. The virus-eriophyid relationship is highly specific; it follows that only rarely the same viral species is transmitted by different eriophyid species and *vice versa*,

Fig. 4 Phylogenetic relationships among emaraviruses. Neighbor joining (NJ) phylogenetic trees generated on the deduced amino acid sequences of the putative RNA-dependent RNA polymerase (RdRP, RNA-1), glycoprotein precursor (GP, RNA-2), nucleocapsid protein (NP, RNA-3) and movement protein (MP, RNA-4). Orthologs of representative members in the genera *Emaravirus*, *Orthotospovirus* and *Orthobunyavirus* are included. Members and tentative members of the emaraviruses reported in the phylogenetic trees are the following: AcCRaV (Actinidia chlorotic ringspot-associated virus), AcEV-2 (Actinidia emaravirus 2), BLMaV (Blackberry leaf mottle-associated virus), CjEV-1 (Camellia japonica associated virus 1), CjEV-2 (Camellia japonica associated virus 2), EMARaV (European mountain ash ringspot-associated virus), FMV (Fig mosaic virus), HPWMoV (High Plains wheat mosaic virus), JYMaV (Jujube yellow mottle-associated virus), PIVB (Pistacia virus B), PPSMV-1 (Pigeonpea sterility mosaic virus 1), PPSMV-2 (Pigeonpea sterility mosaic virus 2), PVBV (Palo verde broom virus), RLBV (Raspberry leaf blotch virus), RRV (Rose rosette virus), RYRSaV (Redbud yellow ringspot-associated virus), TIRSaV (Ti ringspot-associated virus). RNAs accession numbers of emaraviruses are reported in [Table 1](#). TSWV (Tomato spotted wilt virus, AY070212; AY870390; KM365066) and BUNV (Bunyamwera orthobunyavirus, MH091919) were used to root the phylogenetic trees. The bar represents the number of amino acid replacements per site.

i.e., PPSMV-1 and PPSMV-2. This also explains the narrow range of host plants generally infected by each emaravirus. To date, the ascertained virus-vector transmission ratios are those between EMARaV with *Phytoptus pyri*, FMV with *Aceria ficus*, PPSMV-1 and PPSMV-2 with *Aceria cajani*, RLBV with *Phyllocoptes gracilis*, RRV with *Phyllocoptes fructiphilus*, HPWMoV with *Aceria tosichella*, and BPVBV with *Aculus cercidis*. In other cases (BLMaV and RYRSaV) transmission by eriophyid mites is highly suspected, but the exact species responsible has not yet been identified.

Spontaneous host plants in marginal and uncultivated areas contribute to preserving populations of eriophyids and viruses when the sensitive and elective host plant is temporarily unavailable. It has also been observed that eriophyid (*A. cajani*, *A. tosichella* and *P. fructiphilus*) populations are larger on infected plants than on healthy ones.

Eriophyid mites possess a short stylet, with which they can penetrate only epidermal and, at most, the underlying mesophyll cells. Therefore, mites can acquire the disease agent only if it is present in these plant cells. Transmission efficiency increases as the number of individual mites present on the host plant increases. In experimental trials, the efficiency of PPSMV-1 transmission by a single *A. cajani* mite was up to 53% but rose to 100% when more than 5 mites were used per plant. Moreover, *A. cajani* and *A. tosichella* acquired PPSMV-1 and HPWMOV, respectively, after a minimum acquisition access period (AAP) of 15 min (although 50% transmission of HPWMOV was achieved only with an AAP of 16 h) and inoculated virus after a minimum inoculation access period of 90 min. Starvation before or following virus acquisition can reduce these periods. Mites retain viruses for up to 13 h in *A. cajani*, 4 days in *A. tosichella*, and 10 days in *A. ficus*. No latent period was observed with PPSMV-1 in *A. cajani*, whereas a 6–7 h latent period was reported for FMV in *A. ficus*. These data suggest a semipersistent fimoviruses transmission mode. Trans-stadial transmission of the virus was ascertained for *A. ficus* and FMV, *A. cajani* and PPSMV, and *A. tosichella* and HPWMOV. The latter virus is transmitted by all stages of *A. tosichella* and is retained through the molt. However, adults cannot acquire the virus and therefore transmit only if they acquired the virus during their immature stages.

The mechanical transmission of fimoviruses onto herbaceous hosts is rare, and has been shown only for a few species, i.e., AccRaV onto *N. benthamiana*, PPSMV-1 and PPSMV-2 onto *N. benthamiana* and *N. clevelandii*, and TiRaV onto *N. benthamiana*, *N. tabacum* and some cucurbits. The leaf stapling technique was effectively used to transmit PPSMV-1 and PPSMV-2 from infected plants onto *Phaseolus vulgaris*, while mite transmission was used to transmit FMV to *Catharanthus roseus*.

Symptomatology and Economic Impact

Given the novel establishment of this virus family and the recent identification of many of its members, mainly thanks to the use of the innovative NGS technique, it is difficult to determine the actual economic impact of these viruses on crops. For many of them, their effective distribution, apart from the countries where they were first identified, remains unclear, except for FMV, which is ubiquitous. It seems certain, however, that the range of hosts naturally infected by each emaravirus species is rather restricted, due to the high specificity of the relationship between virus/vector/plant.

FMV is the main, if not the exclusive agent of Fig mosaic (FMD), a worldwide fig tree disease first described in 1933. FMV causes many disorders in fig trees: poor fruit quality, reduced productivity and stunted growth (Fig. 1). Given the widespread and great incidence of this disease, the economic impact of FMV should be considered as particularly relevant. Another natural host of FMV outside the genus *Ficus* is the species *Cyclamen persicum*, while members of family *Moraceae*, *Cudrania tricurpidata* and *Morus indica* can be artificially infected.

HPWMOV is the agent of High Plains disease (HPD), an economically important disease of wheat and maize, first found in the Great Plains region of the United States in 1993. Since then, HPD has been reported in different regions of the USA, Australia, and New Zealand. Symptoms on sweet corn consist of stunting, yellowing (chlorosis) and mosaic foliar patterns along veins, which progress into streaking patterns and necrosis. Infected wheat develops severe mosaic symptoms.

PPSMV-1 and PPSMV-2 are the agents of sterility mosaic (SMD), which is the most damaging disease of pigeonpea (*Cajanus cajan*) in the Indian subcontinent (India, Bangladesh, Nepal, Thailand, Myanmar, Sri Lanka and China). SMD is manifested by a wide array of symptoms on pigeonpea (Fig. 1). These include various mosaic patterns on leaves, small misshapen leaves, shoots proliferation, stunting and complete or partial cessation of flower production (sterility), but the disease is not lethal to the host. Plant infection by PPSMVs at an early stage can result in a 95%–100% loss of yield, while losses from late infection depend on the level of infection and range from 26% to 97%. In the 1970s it was estimated that this disease caused annual grain losses worth over \$300 million.

Rose rosette disease (RRD), induced by RRV, is one of the most destructive diseases of cultivated roses in North America, regardless of cultivar. Symptoms were described in the United States as early as 1941. Spread of the disease in the USA was linked to the introduction from Japan of the multiflora rose, an exotic plant used as a rootstock for ornamental roses. Symptoms include excessive lateral shoot growth, excessive thorniness, witches' broom, leaf proliferation and malformation, mosaic, red pigmentation, and eventually plant death.

EMARV mainly infects European mountain ash (*Sorbus aucuparia* L.), a widely distributed indigenous tree in many parts of Europe and the Middle East, widely present in forests, but also frequently cultivated in gardens, public green areas and along avenues. The virus mostly causes chlorotic ringspots and mottling on leaves (Fig. 1), leading to the slow dieback of affected trees within a few years. Its presence has been reported in Austria, the Czech Republic, Sweden, Finland, Germany, Russia, Norway, Poland and the United Kingdom. Other host plants of EMARV apart from *S. aucuparia* have been identified, such as various Rosaceae species and hybrids.

The impact of the other known emaravirus species appears less important; their diffusion seems to be relatively contained at present, their etiological meaning is still uncertain, and they attack ornamental or cultivated plants with less commercial value.

AccRaV infects kiwifruit trees (*Actinidia* spp.), causing leaf ringspots, vein yellowing and chlorotic spots.

BLMaV has been detected in many cultivated and wild blackberries affected by yellow vein, the major constraint for blackberry production in the southern United States.

RYRSaV has been detected in eastern redbud trees (*Cercis canadensis*) grown in Arkansas, which present yellow ringspot symptoms on the leaves. Grafting can artificially infect *Glicine max*, *Phaseolus vulgaris*, *Vigna unguiculata* and *Robinia pseudoacacia* plants.

RLBV is associated with severe raspberry leaf blotch disorder in wild and cultivated *Rubus* spp. plants in many European countries. It is a long-known disease characterized by large yellow blotches or rings on leaves, twisting of the leaves, distortion of leaf margins, leaf malformation, necrosis, and reduced vigor of the severely affected plants.

TiRSaV is a tentative emaravirus responsible for an emerging disease of *Cordyline fruticosa* in Hawaii and produces small chlorotic ringspots on leaves that often coalesce to form larger lesions.

PiVB is a tentative emaravirus infecting symptomless *Pistacia* plants in Turkey.

AcEV-2 is a tentative emaravirus affecting kiwifruit tree showing leaf mottle and chlorosis symptoms in China.

CjEV-1 and CjEV-2 are two tentative emaraviruses found in Italy in infected *Camellia* plants associated to symptoms of chlorotic and necrotic ringspots, deformations and yellowing on leaves, and deformations and color breaking of petals.

JYMaV is a tentative emaravirus found in China associated to Jujube yellow mosaic, a disease characterized by mottling, yellowing and distortion of leaves, malformation and discoloration of fruits, with necrotic areas mainly around the calyx.

LiCRaV is a tentative emaravirus found in China on ornamental shrub common lilac (*Syringa vulgaris* L.), associated to leaf chlorotic ringspots and mottling symptoms.

PVBV is a tentative emaravirus infecting the ornamental plant *Parkinsonia florida* in Arizona, causing witches' broom symptoms.

WBVV is a tentative emaravirus attacking *Arctium* spp. (*Asteraceae*) in Finland.

Diagnosis

In recent years there has been a sharp rise in the number of fimoviruses due to the impulse given using molecular techniques. Of the many such techniques available, Next-generation sequencing (NGS) technology is a powerful tool for the detection of unknown disease-associated viruses and has made a great contribution to the discovery of these viruses. Fimoviruses are easily discernable in the field because of the outstanding symptoms, *i.e.*, typical chlorotic ringspot and mosaic, that they induce in infected plants. However, when are present together with mixed viral infections, the specific recognition of their symptoms may be disorientating.

Their mechanical transmission to herbaceous hosts from infected sap, which is a simple way for recovering viruses, often is unsuccessful. This is due on the one hand to the non-transmissible nature of many of these viruses and on the other hand to the presence of plant inhibitors impeding the success of the inoculation.

In the absence of serological means for the detection of most fimoviruses, except for FMV and PPSMV-1, DNA-based molecular assays with all their various techniques remain the most suitable methods for detecting these viruses. The high number of RNA segments composing the genome and the presence of conserved motifs in many of their genes has led to the development of specific and degenerate primers, which have proved effective in RT-PCR to detect fimoviruses at the species and genus levels, respectively. Furthermore, TaqMan Realtime PCR and LAMP assays have also been developed for FMV and BLMaV, providing a greater sensitivity than conventional RT-PCR assay in the detection of both viruses. At the serological level, immunological detection is based on two different polyclonal antisera raised against the recombinant RNP of FMV and on purified virus particles of HPWMoV and PPSMV-1.

Treatment and Prevention

Given the impossibility of combating virus diseases in the field, control of fimoviruses is essentially preventive. It mostly consists of avoiding the introduction of infected plants that can act as a reservoir for the spread of viruses to healthy plants *via* vectors. Thus, rapid detection of infected plants and their immediate and complete removal, and the elimination of alternative host species, where these exist, (*e.g.*, multiflora roses for RRV, grass-type weeds and volunteer grain crops for HPWMoV) or of infected residues from previous crops (*e.g.*, for RRV and PPSMV) can be very useful in reducing the amount of inoculum.

Good spacing between plants so that leaves do not touch can prevent eriophyid mites from moving within a crop. Containment of the infection at very low levels in the field also serves to delay the onset of the disease and significantly attenuates the extent of symptoms, especially in herbaceous crops (*e.g.*, in the case of PPSMVs, RRV and HPWMoV).

Delayed planting of winter wheat reduces the chance for *Aceria tosichella* to transmit the virus and prevents an overwintering reservoir for HPWMoV. Early season planting of corn has been shown to reduce the effect of HPWMoV infections by allowing the plants to mature before the eriophyid vector becomes active.

The use of genetic resistance sources is one of the most promising approaches in preventing or lessening the impact of fimoviruses. Several varieties of HPWMoV-resistant maize have been identified, although there are no known resistant varieties of wheat, barley, oats or rye. Genetic resistance lines have also been identified regarding pigeonpea by evaluating the behavior of numerous varieties preserved in germplasm collections when infected with PPSMVs.

Control of the eriophyid vectors, mainly involving pesticides, is the other pillar in control of these viruses. Pesticide use alone entails a high level of risk because the eriophyid mite may develop resistance. Therefore, the most effective way to manage fimovirus diseases is a multi-tactic approach that includes both cultural and chemical practices.

Nomenclature

bp	Base pair	nt	Nucleotide
CP	Coat protein	ORF	Open reading frame
CP-RT	Coat protein-readthrough protein	PCR	Polymerase chain reaction
ELISA	Enzyme-linked immunosorbent assay	PD	Plasmodesmata
ER	Endoplasmic reticulum	PME	Pectin methyl-esterase
GFP	Green fluorescent protein	RdRp	RNA-dependent RNA polymerase
HSP	Heat shock protein	RNA	Ribonucleic acid
kDa	Kilodalton	siRNAs	Small-interfering RNAs
MP	Movement protein	ssRNA	Single-stranded ribonucleic acid
NGS	Next generation sequencing	vRNP	Viral ribonucleoprotein
nm	Nanometer	VSR	Viral suppressor of gene silencing

Glossary

Furovirus Siglum from fungus-borne, rod-shaped virus.

Classification

Furoviruses are positive sense, single stranded RNA (ssRNA) viruses in the family *Virgaviridae*. Furoviruses have a bipartite genome and each RNA is encapsidated by a single SBWMV of coat protein (CP). *Soil-borne wheat mosaic virus* (SBWMV) is the SBWMV species of the genus *Furovirus*. The genus *Furovirus* presently comprises six species; *Soil-borne wheat mosaic virus*, *Japanese Soil-borne wheat mosaic virus* (JSBWMV), *Soil-borne cereal mosaic virus* (SBCMV), *Chinese wheat mosaic virus* (CWMV), *Oat golden stripe virus* (OGSV), and *Sorghum chlorotic spot virus* (SrCSV). In 2011, a barley-infecting furovirus named soil-borne barley mosaic virus (SBBMV) was identified. Because of high nt sequence identity to JSBWMV (approximately 94% on RNA2) and the fact that barley is infected as primary host species, we suggest that this virus is classified as strain of the JSBWMV. (Table 1).

Virion Structure

Furoviruses have bipartite genomes which are encapsidated in non-enveloped rod-shaped particles with a helical symmetry and a diameter of approximately 20 nm. The maximum length of the particles ranges between ca. 140–160 nm and 260–300 nm. Due to internal deletions in the CP-readthrough protein genes on RNA2, particles shorter than 140 nm may arise in naturally infected plants and in laboratory isolates at later infection stages or after passage of the virus from plant to plant, and may outcompete the 140–160 nm particles. The furovirus CP has a molecular mass of approximately 20 kDa. Virions occur scattered, or in aggregates or inclusion bodies in the cytoplasm and vacuole of infected cells. Inclusion bodies may be crystalline or consist of clusters of virus particles in association with microtubules. In plants doubly infected by *Sorghum chlorotic spot virus* (SrCSV) and potyviruses, SrCSV virions have been shown to bind to cylindrical inclusions induced by potyviruses present in the same cell.

Nucleic Acid Properties and Differentiation of Furoviruses

The nt sequences of the RNAs of all six furovirus member species have been determined. The RNAs are 5' capped and terminate in a tRNA-like structure. For SBWMV, it has been shown that the tRNA-like structure can be amino acetylated with valine in vitro. The furoviral tRNA-like structure is preceded in the 3' untranslated region by an upstream hairpin and an upstream pseudoknot domain with two to seven possible pseudoknots. The genome organization is rather similar for all furoviruses although there are considerable differences in the nt sequences (Fig. 1). The percentages of sequence identities between SBWMV and CWMV, SBCMV and JSBWMV,

Table 1 List of species in the genus *Furovirus*, family *Virgaviridae*. The SBWMV species is written in bold

Species name	Acronym	# segments	Length (nt)	Accession #
Chinese wheat mosaic virus	CWMV	2	(7147 nt) (3569 nt)	NC_002359 NC_002356
Japanese soil-borne wheat mosaic virus	JSBWMV	2	(3574 nt) (7226 nt)	NC_038851 NC_038850
Oat golden stripe virus	OGSV	2	(3232 nt) (7111 nt)	NC_002357 NC_002358
Soil-borne cereal mosaic virus	SBCMV	2	(7025 nt) (3683 nt)	NC_002351 NC_002330
Soil-borne wheat mosaic virus	SBWMV	2	(7099 nt) (3593 nt)	NC_002041 NC_002042
Sorghum chlorotic spot virus	SCSV	2	(3418 nt) (6878 nt)	NC_004015 NC_004014

**Fig. 1** Phylogenetic trees generated by the DNAMAN software for furoviral RNA1 (A) and RNA2 (B). The Genbank accession numbers are given in parentheses.

respectively, ranges from approximately 70%–77% for RNA1. OGSV and SCSV are more distantly related to SBWMV. For RNA2, SBWMV, JSBWMV, and SBCMV are most closely related. The percentage of sequence identities between the different members of the furoviruses for RNA2 ranges between 67% and 83%. Sequence dissimilarities justify that CWMV and SBCMV may be considered as separate species and that JSBWMV is considered a separate species rather than a strain of SBWMV (Fig. 1). However, the fact that reassortment experiments between RNA1 of JSBWMV and RNA2 of the SBWMV strain of SBWMV yielded an infectious progeny and the observation that the biological properties of the wheat-infecting furoviruses are very similar may be taken as evidence that SBWMV - and JSBWMV as well as CWMV and SBCMV may also all be regarded as distantly related strains of the same species. Moreover, differences at the nt level do not necessarily translate into differences at the aa level as exemplified with the CP sequences of the New York and Nebraska strains of SBWMV, which are 100% identical at the aa level, despite the fact that their coding regions differ in 68 nt positions.

Organization of the Genome and Properties of the Encoded Proteins

Furoviral RNA1 codes for two replication-associated proteins of approximately 150 kDa and 209 kDa and for a 37 kDa movement protein (MP) (Fig. 2). The shorter of the two replication-associated proteins contains methyl-transferase and helicase motifs. The longer one results from the read-through of a stop codon and contains the RNA-dependent RNA polymerase (RdRp) in addition to the methyl-transferase and helicase domains. Over-expression experiments using fluorescent protein tagged CWMV replicase showed that it localized to membrane-associated inclusions leading to the hypothesis that virus replication might occur on these host membranes. However, the identity of the host membranes was not further investigated. The CWMV replicase was also shown to interact with heat shock proteins (HSP) of the HSP70 family. The furovirus 37 kDa MP belongs to the '30K' superfamily of viral MPs. Experimental evidence for the function of the CWMV 37 kDa protein as MP came from studies showing that the green fluorescent

Fig. 2 Genome organization of SBWMV. The RNAs are capped and possess a t-RNA structure at the 3' end. RNA1 contains the genetic information for two replicase proteins, the 150K protein containing methyltransferase (Mtr) and helicase (Hel) domains and the 209K protein containing in addition the RNA-dependent RNA polymerase (RdRP) domain. A 37K MP is encoded by ORF2. RNA2 encodes for a 19K major CP, a 25K minor CP initiated at an upstream CUG start codon, a 84K CP-RT protein and a 19K cysteine-rich silencing suppressor.

protein (GFP)-labeled 37 kDa CWMV MP moves from cell to cell when bombarded into wheat leaf cells and can trans-complement the intercellular spread of potato virus X. Moreover, CWMV MP exhibits plasmodesmata (PD) labeling and forms endoplasmic reticulum (ER)-derived vesicular and aggregate structures. Export from the ER appears to be required for intracellular movement and depends on the secretory pathway. Moreover, the CWMV MP interacts with host pectin methyl-esterase (PME), a host cell-wall modifying enzyme, which has been shown to interact with a variety of MPs of the '30K' superfamily. In the case of tobacco mosaic virus, it has been shown that interaction between MP and PME is important for virus movement.

Furoviral RNA2 contains the genetic information for the approximately 20 kDa major coat protein (CP), an approximately 24 kDa minor CP initiated at an upstream CUG start codon, an approximately 84 kDa CP-readthrough (CP-RT) protein and an approximately 19 kDa cysteine-rich protein. Neither the CP with N-terminal extension nor the CP-RT are required for SBWMV and CWMV virion formation and systemic infection. The 24 kDa N-terminally extended CP may be incorporated into virus particles, as it has been detected in purified CWMV virions. For SBCMV and CWMV, the 24 kDa extended CP, but not CP itself, has been shown to interact with the CWMV 19 kDa RNA silencing suppressor. In the case of SBWMV, both CP forms were able to interact with CWMV P19. As silencing activity was not significantly affected by the interaction, a function of the interaction between forms of CP and P19 in silencing suppression cannot be deduced.

Despite dispensable for virion assembly and systemic infection, CP-RT can be associated with virions, as CWMV CP-RT was detected on the surface of virus particles by immunogold labeling. The CP-RT protein of furoviruses appears to be involved in vector transmission, similar to the CP-RT proteins of beny- and pomoviruses. Prolonged cultivation of field-infected plants, virus propagation by repeated mechanical inoculations or growth at elevated temperatures result in spontaneous deletions within the CP-RT domain. These mutants can no longer be transmitted by the vector. Two highly conserved trans-membrane domains within CP-RT proteins are thought to be involved in vector transmission by facilitating the transport of the virion or infectious viral ribonucleoprotein complex across the plasmodiophorid membrane into the host cell cytoplasm.

The CP-RT protein also appears to affect symptom development as spontaneous mutations occurring in SBWMV CP-RT or engineered mutations affecting expression of the CP-RT protein in infectious CWMV clones increased symptom severity. Interestingly, mutations affecting expression of the N-terminally extended minor CP slowed symptom development for CWMV and SBWMV, thus indicating that the different CP-variants and the ratio of the different CP-forms produced may be involved in fine-tuning the infection cycle.

The cysteine-rich 19 kDa protein acts as a suppressor of RNA silencing (VSR) and enhances symptom severity. For the CWMV protein it has been shown that it localizes to the ER and is capable to self-interact. Self-interaction, but not ER-localization correlates with VSR activity of the protein. Residues important for protein stability, silencing suppression activity, symptom development, as well as targeting to the ER have been identified. The exact mode of action of the furovirus VSR is as yet unknown; however, for the CWMV CRP, it appears not to be related with local siRNA production and accumulation. Instead, CWMV CRP protein appears to promote viral cell-to-cell spread, possibly by interfering with the spread of RNA silencing signals ahead of

infection, as movement of a heterologous virus, whose movement depends on the presence of a functional silencing suppressor to be provided in trans, is complemented in the presence of over-expressed CWMV CRP. The localization of the CWMV CRP protein to the ER may be important for symptom development.

Virus Transmission and Movement

Furoviruses are soil-borne. SBWMV has been demonstrated to be transmitted by the zoospores of *Polymyxa graminis*, a ubiquitous plasmodiophorid protozoan. *P. graminis* is probably also the vector for the other viruses in the genus. Polymyxa-transmitted viruses are believed to be taken up by the plasmodia of the vector in infected root cells. The multinucleate plasmodia, which are separated from the host cytoplasm by a distinct membrane, may either develop into zoosporangia from which secondary viruliferous zoospores are released. Alternatively, the plasmodia may develop into cytosori, in which resting spores mature. These resting spores are released into the soil from decaying plant material and may survive in the soil for many years even under extreme conditions. Spores are distributed by agricultural equipment, by irrigation or even by wind. Upon germination, they release primary zoospores transmitting the virus. Zoospores inject their contents into the cytoplasm of root cells and initiate infection by the formation of plasmodia. Zoospores treated with antisera to SBWMV or resting spores treated with 0.1 N NaOH or HCl retained their ability to transmit the virus, indicating that the infectious viral material is present inside the spores. Immunolabeling and in situ RNA hybridization studies have revealed the presence of SBWMV MP and RNA but not of SBWMV CP in the resting spores of *P. graminis*, indicating that SBWMV may be transmitted in form of viral ribonucleoprotein (vRNP) complexes. Moreover, the presence of viral RNAs and MP may indicate that the virus is able to replicate inside the vector. Transmission in form of a vRNP complex containing viral MP and RNA may have the advantage, that the RNA can be directly transported from the primarily infected cell into adjacent cells for the initiation of virus replication and thus, competition between virus and vector for reprogramming of host cell metabolism for replication may be avoided. The '30K' superfamily of MPs, to which the furovirus MPs belong, are known to mediate cell-to-cell and vascular transport of viruses by binding viral nucleic acids and carrying them through plasmodesmata and through the vasculature. However, with respect to systemic movement, SBWMV may use the xylem in order to move from infected roots to the leaves as suggested from light and electron microscopy experiments. The virus may enter primary xylem elements before cell death occurs. Moreover, the virus may move laterally between adjacent xylem vessels.

Symptoms, Epidemiology and Host Range

SBWMV is known since the early 1920s. It causes chlorotic leaf streaking, stunting, and severe losses of yield in winter wheat. SBWMV is widely distributed in the USA and Canada, mainly in the east and has been reported to occur in Europe in Great Britain, Germany, and Poland. It has also been described to occur in Brazil, Africa (Zambia), and Japan. Two types of SBWMV are described, the original "Nebraska-like" SBWMV and a "New York-like" SBWMV. Symptoms often occur in patches in the fields. SBWMV naturally infects wheat, barley, rye, and triticale. An additional strain of SBWMV naturally infecting barley and wheat, termed Japanese soil-borne wheat mosaic virus, has been identified in Japan (SBWMV-JP), France (SBWMV-FR), and Germany (SBBMV-DE). Diseases on wheat with symptoms similar to those described for SBWMV are caused by CWMV in China and SBCMV in Europe. Apart from wheat, SBCMV naturally also infects rye and triticale. SBCMV occurs in a number of European countries including Denmark, Great Britain, Belgium, Poland, Ukraine, France, Italy, Germany, and Turkey. SBCMV occurs in different SBWMV with different aggressivity on wheat. In Italy, France, England, Belgium, and Denmark, wheat becomes heavily infected, while SBCMV in Germany and Poland usually develops weaker symptoms in wheat.

OGSV causes yellow striping on leaves and has been detected in oats in Great Britain, France, and the USA. SBWMV, SBCMV, CWMV, and OGSV may be transmitted mechanically to some species of the *Chenopodium* and *Nicotiana* genus.

SrCSV was isolated in 1986 Kansas/USA. It is mechanically transmissible to maize where it produces a bright yellow mosaic and elongated ringspot symptoms several weeks after inoculation. Local infections are produced on mechanically inoculated *Chenopodium quinoa*, *C. amaranticolor*, and *Nicotiana clevelandii*. Attempts to transmit the virus back to *Sorghum bicolor* or to winter wheat either mechanically or by growing plants in soil, in which infected sorghum was growing, were unsuccessful.

Plants naturally infected by furoviruses are often also infected by bymoviruses, that is, Wheat spindle streak mosaic virus in Europe and North America, Wheat yellow mosaic virus in East Asia or Oat mosaic virus in Europe and the USA. The symptoms caused by these bymoviruses are very similar to those caused by the furoviruses, and both, the furoviruses and the bymoviruses are transmitted by *P. graminis*.

Diagnosis

Visible symptoms caused by furoviruses may vary depending on environmental conditions, such as moisture and temperature as well as dependent on the plant cultivar. Nutrient deficiencies, winter injury or other viruses (especially bymoviruses), may produce symptoms that are easily confused with those caused by furoviruses. Thus, serological or molecular biological techniques are the methods of choice for reliable virus detection. Serological tests such as the enzyme-linked immunosorbent assay (ELISA), tissue

print immunoassay, and immunoelectron microscopy as well as polymerase chain reaction (PCR) techniques are established for the specific detection and discrimination of the viruses. Real-time reverse transcriptase-PCR (RT-PCR) based on intercalation dyes and TaqMan probes have been developed for SBCMV and allow the quantification of virus titer within the tested plants. In the case of Next generation sequencing (NGS) it is possible to identify a virus in a sample without a priori sequence information.

Control

Furoviruses inside the long-living resting spores of *P. graminis* may survive for decades. Growing resistant or tolerant varieties currently represents the only practical and environmentally friendly means to lower the impact of these diseases on yield. Furovirus resistance appears to be quantitative and more than one gene appears to control the resistance phenotype. The only resistance genes known to date to be effective against furoviruses in wheat are the *Sbm1* gene located on chromosome 5DL and the *sbm2* gene located on chromosome 2BS. Both genes confer the so called “translocation resistance”, in which roots still become infected but the virus is inhibited to efficiently infect the shoots of the plants. Although disease symptoms are reduced in the resistant plants, virus ingress into the soil remains unaffected, thus necessitating the development of additional resistance strategies to control these viruses. Cereal genotypes with resistance to *P. graminis* have so far not been identified.

Similarities and Dissimilarities with Other Taxa

The morphology of furoviruses resembles that of other rod-shaped viruses, i.e., of benyviruses, pecluviruses, pomoviruses, hordeiviruses, tobnaviruses, and tobamoviruses. The CPs of all these viruses have a number of conserved residues. Furoviruses, pecluviruses and tobnaviruses have bipartite genomes. Furoviruses differ from pecluviruses by having their movement function encoded on a single ORF rather than a triple gene block. They also differ from pecluviruses as well as from tobnaviruses by having a CP-RT gene. The gene for their cysteine-rich protein is located on RNA2, whereas with pecluviruses and tobnaviruses it is located on RNA1. The cysteine-rich proteins of furoviruses, pecluviruses, and tobnaviruses act as suppressors of post-transcriptional gene silencing and are phylogenetically interrelated. Furoviruses encode two N-terminally overlapping replication-associated proteins (Fig. 2), which are related to those of pomoviruses, pecluviruses, tobnaviruses, and tobamoviruses. The 37 kDa MP of the furoviruses belongs to the ‘30K’ superfamily of MPs and relates the furoviruses to the dianthoviruses and the tobamoviruses, whereas the valine-accepting tRNA-like structure on the 3′ ends of furovirus RNAs relates them to the tymoviruses. Furoviruses like tobamoviruses have an upper pseudoknot domain in the 3′ untranslated regions of their genomic RNAs.

Glossary

CRISPR-Cas The acronym for Clustered Regularly Interspaced Short Palindromic Repeat-CRISPR-associated protein, an adaptive immune system used by bacteria and archaea against viruses and mobile genetic elements, which has been adapted for genome editing in eukaryotes.

Emerging disease A disease of infectious origin that has appeared in a population for the first time, or that has rapidly increased in incidence or geographic range.

Geminate virion A type of twinned virions unique to geminiviruses consisting of two joined, incomplete T=1 icosahedra.

Nucleic acid satellites Subviral agents depending on helper viruses for their replication and/or transmission;

those associated to geminiviruses (alphasatellites, betasatellites and deltasatellites) are circular single stranded DNA molecules.

Pseudorecombination A particular type of genetic exchange which involves swapping of complete genome segments that make up the segmented viral genomes, as bipartite geminivirus genomes.

Recombination A process in which exchange of genome segments occurs between DNA (or RNA) molecules during replication.

Rolling circle amplification A technique that allows amplification of circular DNA molecules (as geminivirus genomes) with $\phi 29$ DNA polymerase and random primers under isothermal conditions.

Introduction

Geminiviruses (family *Geminiviridae*) are a large group of plant viruses that possess small circular single-stranded (ss) DNA genomes encapsidated in unique twinned (geminate) virions. Many geminiviruses cause economically important diseases to vegetable and fiber crops worldwide, although major losses are caused in tropical and subtropical regions. Many others are found infecting weeds and other wild plant species which, in turn, are potential reservoirs for geminivirus emergence. A geminivirus is thought to have been responsible for an unseasonal change in the appearance of eupatorium plants – autumnal yellowing in summer – described in a poem by the Empress Koken in Japan in 752 CE. Thus, geminiviruses are probably the cause of the first record of a viral disease in plants.

With nine recognized genera and a number of species approaching 500, the family *Geminiviridae* is revealed as the plant virus family with the greatest evolutionary success. Their members infect both dicot and monocot species and use as vectors a wide range of insects including whiteflies, aphids, leafhoppers, and treehoppers.

The present entry focuses on current knowledge about viruses in the family *Geminiviridae*, dealing with taxonomy, phylogeny, evolution, genome structure and expression, diagnosis, pathogenesis, epidemiology and control.

Taxonomy, Phylogeny, and Evolution

Genus demarcation criteria in the family *Geminiviridae* include host range (monocots or dicots), type of vector (aphids, leafhoppers, treehoppers, whiteflies), genome organization (monopartite or bipartite) and phylogenetic relationships. Currently, geminiviruses are classified in nine genera: *Becurtovirus*, *Begomovirus*, *Capulavirus*, *Curtovirus*, *Eragrovirus*, *Grablovirus*, *Mastrevirus*, *Topocuvirus* and *Turncurtovirus*, briefly described below ([Table 1](#)).

Table 1 Classification of members of the family *Geminiviridae* into genera, with indication of type member, number of virus species, number of DNA genome components, transmission vector and host type

Genus	Type species	Acronym	Number ^a	Genome	Vector	Host type
<i>Becurtovirus</i>	<i>Beet curly top Iran virus</i>	BCTIV	3	Monopartite	Leafhoppers	Dicots
<i>Begomovirus</i>	<i>Bean golden yellow mosaic virus</i>	BGYMV	409	Monopartite/bipartite	Whiteflies	Dicots
<i>Capulavirus</i>	<i>Euphorbia caput-medusae latent virus</i>	EcmLV	4	Monopartite	Aphids	Dicots
<i>Curtovirus</i>	<i>Beet curly top virus</i>	BCTV	3	Monopartite	Leafhoppers	Dicots
<i>Eragrovirus</i>	<i>Eragrostis curvula streak virus</i>	ECSV	1	Monopartite	Unknown	Monocots
<i>Grablovirus</i>	<i>Grapevine red blotch virus</i>	GRBV	3	Monopartite	Treehoppers	Dicots
<i>Mastrevirus</i>	<i>Maize streak virus</i>	MSV	40	Monopartite	Leafhoppers	Monocots/Dicots
<i>Topocuvirus</i>	<i>Tomato pseudo-curly top virus</i>	TPCTV	1	Monopartite	Treehoppers	Dicots
<i>Turncurtovirus</i>	<i>Turnip curly top virus</i>	TCTV	2	Monopartite	Leafhoppers	Dicots

Fig. 1 Symptoms caused by the begomoviruses Tomato yellow leaf curl virus in tomato (A), the complex Tomato yellow leaf distortion virus and Tomato yellow leaf distortion deltasatellite 1 in the wild plant *Sidastrum micranthum* (B) and African cassava mosaic virus in cassava (C), and the mastrevirus Chickpea chlorotic dwarf virus in chickpea (D). (D) Reproduced from Kanakala, S., Kuria, P., 2019. Chickpea chlorotic dwarf virus: An emerging monopartite dicot infecting mastrevirus. Viruses 11, 5, CC BY 4.0 licence.

Becurtovirus

This genus includes three recognized species, *Beet curly top Iran virus*, *Exomis microphylla latent virus* and *Spinach curly top Arizona virus*. Members of all species are monopartite viruses transmitted by leafhoppers to dicot plants.

Begomovirus

This genus, with 409 accepted species, is the largest in the entire virosphere. Its members infect dicot plants and are transmitted by whiteflies of the *Bemisia tabaci* cryptic species complex. The genome can be either bipartite or monopartite. Begomoviruses usually induce severe symptoms in their hosts, including yellow/golden mosaics, leaf curl/deformation, yellow veins and stunting (**Fig. 1(A)–(C)**). Devastating viruses include members of the species *African cassava mosaic virus*, *Bean golden yellow mosaic virus*, *Cotton leaf curl Multan virus*, and *Tomato yellow leaf curl virus*. Three classes of circular ssDNA satellites have been described associated with begomoviruses: alphasatellites, betasatellites, and deltasatellites.

Capulavirus

This genus includes four species, members of which have monopartite genomes. Members of the species *Alfalfa leaf curl virus* are transmitted by the aphid *Aphis craccivora*.

Curtovirus

This genus includes three recognized species, including *Beet curly top virus*, whose members are economically important pathogens in North America and Iran and have the widest host range of any geminivirus (over 300 species reported in over 40 dicot plant families). Members are transmitted by leafhoppers.

Eragrovirus

This genus includes a single species, *Eragrostis curvula streak virus*, members of which have monopartite genomes. All known isolates have been found infecting the monocot plant weeping lovegrass (*Eragrostis curvula*) in South Africa. The vector of the only known eragrovirus remains unknown.

Grablovirus

This genus includes three species, members of which have monopartite genomes and infect *Vitis* and *Prunus* spp. Members of *Grapevine red blotch virus* are transmitted by the three-cornered alfalfa treehopper, *Spissistilus festinus*.

Mastrevirus

This genus include 40 species, members of which have monopartite genomes, infect mostly monocots and some dicots, and are transmitted by several species of leafhoppers. It is worth mention *Maize streak virus* and *Chickpea chlorotic dwarf virus*, members of which cause severe diseases of maize in Africa and chickpea (**Fig. 1(D)**) and other crops in Africa and Asia, respectively. Recently, members of *Wheat dwarf India virus* have been shown to have associated alphasatellites and betasatellites.

Topocuvirus

Members of the single species in this genus, *Tomato pseudo-curly top virus*, have monopartite genomes, infect dicots and are transmitted by the treehopper *Micrutalis malleifera*.

Turncurtovirus

This genus include two species, members of which have monopartite genomes and have been isolated from symptomatic turnip (*Brassica rapa*) or radish (*Raphanus sativus*) plants from Iran, being transmitted by the leafhopper *Circulifer haematocaps*.

Also, two unassigned species in the family *Geminiviridae* have been recognized, *Citrus chlorotic dwarf associated virus* and *Mulberry mosaic dwarf associated virus*.

Phylogenetic analysis of complete genome sequences (DNA-A sequences for bipartite genomes) from isolates of representative species shows that geminiviruses group in clusters corresponding to the nine existing genera (**Fig. 2**). In addition, they are grouped to some extent according to geographic distribution, at least within the begomoviruses, probably reflecting their evolutionary divergence as a consequence of isolation. Begomoviruses can be classified into four lineages: Old World (OW) begomoviruses, New World (NW) begomoviruses, sweepoviruses and legumoviruses. OW and NW begomoviruses are originated from the Old World (Africa, Asia, and Europe) and the New World (The Americas), respectively. OW begomoviruses can have monopartite or bipartite genomes whereas most of the NW begomoviruses have bipartite genomes. A few exceptions of monopartite begomoviruses natives to the NW exist, including tomato leaf deformation virus, reported from Peru and Ecuador. Legumoviruses are restricted to legumes from Asia and Africa and most of them have bipartite genomes. Sweepoviruses infect sweet potato (*Ipomoea batatas*) and other members of the family Convolvulaceae and have monopartite genomes. Sweepoviruses seem to have diverged prior to the separation between the Old World and the New World begomovirus branches, seeming to represent one of the earliest points of divergence among this genus.

Genetic diversity and evolution of geminiviruses are driven by mutation, recombination and pseudorecombination (reassortment of genome components) which contribute significantly to the appearance of new viral variants, increasing their potential of adaptation to different hosts and environmental conditions. Recombination, a process in which exchange of genome segments occurs between DNA strands during replication, is common among members of the family *Geminiviridae*, notably among members of the genus *Begomovirus*, contributing greatly to genetic diversification of viral populations and speciation. Replication of geminiviruses, in addition to a rolling-circle replication (RCR) mechanism, also involves a recombination-dependent replication (RDR) mechanism. RDR provides a tool by which damaged or incomplete geminivirus DNA could be recovered for productive infection by homologous recombination and converted into full-size genomic DNA. The existence of this mechanism might explain in part the extent at which recombination is shaping geminivirus populations. Recombination in geminiviruses has been shown to occur either at the strain, species, genus and family levels. Many studies have reported that an important number of begomovirus epidemics are directly linked to recombinant viruses, for example, cassava mosaic disease in Africa, tomato yellow leaf curl disease in the Mediterranean basin and cotton leaf curl disease in the Indo-Pakistan sub-continent.

Fig. 2 Neighbor-joining phylogenetic tree of the full genome sequences (or DNA-A sequences for bipartite geminiviruses) of representative isolates of all genera (*Becurtovirus*, *Begomovirus*, *Capulavirus*, *Curtovirus*, *Eragrovirus*, *Grabovirus*, *Mastrevirus*, *Topocuvirus*, and *Turncurtovirus*) and unassigned species in the family *Geminiviridae*. OW (Old World), Legumo (legumoviruses), NW (New World) and Sweepo (sweepoviruses) are the four phylogenetic groups in the genus *Begomovirus*. Bootstrap values (1000 replicates) are shown. Viruses used to generate the phylogenetic tree are as follows: ACMV, African cassava mosaic virus; ALCV, Alfalfa leaf curl virus; BCTIV, Beet curly top Iran virus; BCTV, Beet curly top virus; BGYMV, Bean golden yellow mosaic virus; CCDaV, Citrus chlorotic dwarf associated virus; CLCuKov, Cotton leaf curl Kokhran virus; CpCDV, Chickpea chlorotic dwarf virus; DesMoV, Desmodium mottle virus; EcmLV, Euphorbia caput-medusae latent virus; ECSV, Eragrostis curvula streak virus; GRBV, Grapevine red blotch virus; HrCTV, Horseradish curly top virus; MMDaV, Mulberry mosaic dwarf associated virus; MSV, Maize streak virus; PILV, Plantago lanceolata latent virus; SCTAV, Spinach curly top Arizona virus; SPLCV, Sweet potato leaf curl virus; TCTV, Turnip curly top virus; TPCTV, Tomato pseudo-curly top virus; TYLCV, Tomato yellow leaf curl virus; WDV, Wheat dwarf virus. The bar below the tree indicates nucleotide substitutions per site.

Virion Structure

Geminiviruses have evolved a unique capsid structure. Virions are typically twinned or “geminate” particles of 22×30 nm which give the virus family its name. They consist of two joined, incomplete $T=1$ icosahedra (hemiscapsids) (Fig. 3). Cryo-electron microscopy (EM) has shown that virions of the begomovirus African cassava mosaic virus, and the mastrevirus maize streak virus containing 110 coat protein (CP) subunits organized as 22 pentameric capsomers. Cryo-EM structure at 3.3 Å resolution has further shown that the

capsid of the begomovirus *ageratum* yellow vein virus is built from three distinct conformations of a single CP, and that these conformational differences facilitate the formation of the interface between hemicapsids. Each twinned virion contains a single copy of circular ssDNA. Thus, for viruses with bipartite genomes, two virions containing different genomic components are required for infection. Defective genome components and ssDNA satellites associated with begomoviruses have also been found to be encapsidated.

Genome and Viral Proteins

Geminivirus genomes contain coding regions in both virion-sense and complementary-sense strands diverging from an intergenic region (IR) that includes the origin for RCR. Transcription is bi-directional, with independently controlled transcripts initiating within the IR. Multiple overlapping transcripts are used by geminiviruses for gene expression and transcript splicing is also used by members of the genus *Mastrevirus* and probably also by becurtoviruses, capulaviruses, and grabloviruses. The best-characterized genomes of geminiviruses are those of members of genera *Begomovirus*, *Curtovirus*, and *Mastrevirus*. Fig. 4 shows the genome organization of representative members of the nine genera in the family *Geminiviridae*. The genome of begomoviruses, the largest and more studied group in the family, is described more in detail below.

The genomes of bipartite begomoviruses consist of DNA-A and DNA-B components, each of 2.5–2.7 kb. Both genome components share an approximately 200 nt segment (common region, CR) within the IR that includes the origin of replication. The genomes of monopartite begomoviruses resemble the bipartite DNA-A component. DNA-A and monopartite genomes have six open reading frames (ORFs), two in the virion sense (AV1/V1 and AV2/V2) and four in the complementary sense (AC1/C1 to AC4/C4). DNA-B has two ORFs, the virion-sense BV1 and complementary-sense BC1. DNA-A and monopartite genomes encode a coat protein (CP, ORF AV1/V1), a protein putatively involved in viral movement (ORF AV2/V2, absent in bipartite New World begomoviruses), a replication-associated protein (Rep, ORF AC1/C1), a transcriptional activator (TrAP, ORF AC2/C2), a replication enhancer (REn, ORF AC3/C3), and C4 protein (ORF AC4/C4). DNA-B encodes a nuclear shuttling protein (NSP, ORF BV1) and a movement protein (MP, ORF BC1).

The CP is the only structural protein of geminivirus particles and, in addition to form the viral capsid, has been associated with other functions as insect transmission, shuttling of viral DNA into and out of the nucleus and cell-to-cell and systemic spread of the virus in for monopartite viruses. ORF AV2/V2 starts upstream ORF AV1/V1 and encodes for a protein whose exact function is uncertain, although in the case of at least some monopartite begomoviruses it is a movement protein. Rep is a multi-functional protein essential for viral DNA replication by initiating (endonuclease activity) and terminating (ligase activity) RCR. For that, Rep binds to dsDNA during origin recognition and introduces a nick in a highly conserved nonanucleotide (TAATATTAC) contained within a stem-loop structure that is part of the origin of replication. TrAP protein activates the transcription of the genes coding for CP and MP proteins. REn protein, although not essential for virus preplication, enhances viral DNA accumulation. ORF AC4/C4 is contained entirely within ORF AC1/C1, but in a different frame, and C4 proteins are the least conserved of all geminivirus proteins, having diverse functions including virus movement and are involved in symptom development. In addition to their specific functions, C4, TrAP and V2 proteins have been shown to suppress transcriptional (TGS) and post-transcriptional gene silencing (PTGS), whereas Rep protein suppresses TGS. In the DNA-B, BV1 encodes the NSP required for trafficking viral ssDNA between the nucleus and the cytoplasm in the form of a viral DNA–NSP complex. For cell-to-cell and long-distance movement, the NSP–viral DNA complex is trapped by the MP (encoded by BC1) in the cytoplasm and redirected to adjacent cells, where NSP directs the viral genome to the nucleus to initiate replication again.

DNA Satellites Associated With Geminiviruses

Three types of circular single-stranded DNA satellites are associated with begomoviruses, alphasatellites, betasatellites, and deltasatellites. Alphasatellites and betasatellites are about half size begomovirus genome components whereas deltasatellites are about half size alphasatellites and betasatellites. Alphasatellites are mainly associated with monopartite Old World begomoviruses but also with some bipartite New World begomoviruses. They encode a Rep protein needed for their replication with similarity with the Rep encoded by nanoviruses (family *Nanoviridae*). Betasatellites are associated with many monopartite Old World begomoviruses and are essential for induction of typical disease symptoms. The β C1 protein encoded by the betasatellites has important roles in symptom induction, suppression of transcriptional and post-transcriptional gene silencing, and can affect jasmonic acid responsive genes. Only in one case alphasatellites and betasatellites have been found associated with a *mastravirus*, Wheat dwarf India virus. Deltasatellites have been found associated with bipartite Old World begomoviruses, monopartite Old World begomoviruses and sweepoviruses. Deltasatellites do not encode for any protein and, although in some cases reduce the accumulation of the helper begomovirus, rarely modify the symptoms caused by the begomovirus. All these satellites depend on their helper begomoviruses for replication (except alphasatellites), cell-to-cell and systemic spread throughout the plant, encapsidation, and transmission to new host plants by insect vectors.

Diagnosis

There are a number of leaf symptoms typically associated with geminivirus – mainly begomovirus – infection, including yellow and golden mosaics, leaf curl and deformation and vein yellowing. Also, monocots infected with *mastraviruses* use to show typical

Fig. 4 Genome organization of representative members of the nine genera in the family *Geminiviridae*. ORFs are color-coded according to the function of their protein products (rep, replication-associated protein; ren, replication enhancer protein; trap, transcriptional activator protein; cp, capsid protein; mp, movement protein; nsp, nuclear shuttle protein). Old World bipartite begomoviruses contains ORF AV2, not shown in the figure. LIR, long intergenic region; SIR, short intergenic region; CR, common region. The hairpin which includes the origin of replication is indicated in the LIR. Reproduced with permission from Varsani, A., Roumagnac, P., Fuchs, M., *et al.*, 2017. Capulavirus and Grablovirus: Two new genera in the family Geminiviridae. Archives of Virology 162, 1819–1831.

leaf streaks and striates. However, these symptoms, although suggestive of geminivirus infection, may be caused by other viruses, and rarely they can be used to identify the specific virus involved. Thus, diagnosis based on symptoms alone is not sufficient and specific diagnostic tests must be used to confirm geminivirus infection. For some geminiviruses, such as the begomoviruses *African cassava mosaic virus* and *Tomato yellow leaf curl virus* or the curtovirus *Beet curly top virus*, antibodies against the coat protein have been generated to be used in serological tests. However, although in some cases antisera have been commercialized, they are not commonly used for diagnosis because the presence of common epitopes in the coat protein hinder them to be used for specific virus identification.

DNA-based methodologies have allowed the development of rapid and specific tests for detection and characterization of geminiviruses. From dot- and squash-blot hybridization using cloned geminivirus DNAs as probes to polymerase chain reaction (PCR) technologies, a wide range of methods have revolutionized the diagnosis of geminiviruses. PCR can be considered currently the method of choice for geminivirus detection due to sensitivity, specificity and rapidity. Also, PCR can be adapted to detection of a specific virus or a group of them. Sequencing of PCR products can be used later for precise identification of the virus. Loop-mediated isothermal amplification has been also used to develop tests for a number of geminiviruses.

Rolling circle amplification (RCA), which amplifies circular DNA molecules in a nonspecific manner using random primers and $\phi 29$ DNA polymerase, coupled with restriction enzyme digestion, has resulted recently in a valuable and powerful tool for cloning of uncharacterized geminiviruses. More recently, next-generation sequencing (Roche 454, Illumina, Ion Torrent, etc.) has become increasingly accessible, allowing characterization of mixed infections and readily discovery of novel geminiviruses. Nanopore-based platforms, including portable versions, are also being used in metagenomic studies applied to the discovery of geminivirus diversity.

Life Cycle

Geminiviruses, exemplified by begomoviruses, initiate infection when an insect vector (whitefly) carrying the virus feeds on the sap transported through the phloem of a healthy leaf and transmits virions to phloem-associated cells (Fig. 5). In the plant cell, viral ssDNA is released from virions and, since geminiviruses do not encode a DNA polymerase, it is copied by host DNA polymerases to generate double-stranded (ds) DNA. The dsDNA is transcribed by host RNA polymerase II, allowing the production of Rep. This protein initiates viral replication, which occurs by a combination of RCR and RDR mechanisms. Nascent circular ssDNA can be converted to dsDNA to re-enter the replication cycle. Later in infection, Rep represses its own transcription, leading to activation of transcriptional activator protein (TrAP) expression, which in turn activates coat protein (CP) and nuclear shuttle protein (NSP) expression. Circular ssDNA can then be encapsidated by CP into virions, which are available for insect vector acquisition. The infection is propagated inside the plant by the movement of viral DNA out of the nucleus into the next cell or the phloem through the action of two viral movement proteins, nuclear shuttle protein (NSP) and movement protein (MP).

An important phase of the begomovirus life cycle is the transmission between plants by the insect vector, the whiteflies of the *B. tabaci* complex. For that, begomoviruses need first to cross the midgut wall to reach the hemolymph and then accumulate in the primary salivary glands, from where they are secreted in the saliva to infect new plants. The transport across midgut wall and

Fig. 5 The geminivirus life cycle, exemplified by begomoviruses. See main text for details.

through primary salivary glands are key steps determining differential transmission in different whitefly-begomovirus combinations. Although whether circulative begomovirus transmission is non-propagative (the virus does not replicate in the whitefly) or propagative (the virus replicates in the whitefly) has been a topic of debate, there is accumulating evidence that at least Tomato yellow leaf curl virus (TYLCV) is able to replicate within *B. tabaci*. Certain begomoviruses have been also shown to be transmitted transovarially to the descendance. From the virus side, the CP has been found to be the sole determinant of the persistent transmission of begomoviruses by *B. tabaci*. Inside the whiteflies, the transmission also involves certain endosymbiotic bacteria. For instance, it has been shown that transmission of TYLCV depends on chaperonin GroEL homologs produced by endosymbiotic bacteria, which have been proposed to protect the virus from degradation during passage through the hemolymph.

Pathogenicity

Although the information about how geminiviruses cause diseases in their host plants is very limited, there are a number of cases in which the mechanisms involved in the production of symptoms has been studied. Determinants of pathogenicity include C4, TrAP, V2, and NSP proteins encoded by different begomoviruses and curtoviruses. C4 encoded by the curtovirus Beet curly top virus, for example, is the major determinant of the characteristic vein swelling phenotype observed in infected plants caused by abnormal cell division. In this case, C4 induces the expression of RKP, a RING finger E3 ligase, which may be involved in cell cycle regulation. Another well studied case is that of NSP encoded by the begomovirus Tomato leaf curl New Delhi virus (ToLCNDV) which is an avirulence determinant inducing a hypersensitive response (HR) in tomato (*Solanum lycopersicum*) and tobacco (*Nicotiana tabacum*). ToLCNDV TrAP is also a pathogenicity factor which may counter NSP-induced HR in infected cells. The involvement of NSP in virus pathogenicity is supported by its interactions with membrane receptor kinases implicated in a wide range of signal transduction pathways. On the other hand, TrAP compromises the ability of COP9 signalosome (a protein complex that functions in the ubiquitin-proteasome pathway) to bind to Cullin-1 (CUL1), an essential component of the SCF (SKP1, CUL1/CDC53, F box proteins) ubiquitin E3 ligase complex; TrAP-COP9 interaction alters the cellular processes regulated by SCF complexes, including jasmonate signaling, thereby regulating host response to infection.

Control

Many factors affect the occurrence and prevalence of geminivirus diseases and the losses they cause to crops worldwide. As for plant viruses in general and particularly for those transmitted by an insect vector, control of diseases caused by geminiviruses would benefit from the application of integrated pest management (IPM) strategies, which take in account all those factors. Some of the general strategies that can be used with more or less success to manage geminivirus diseases and epidemics are considered below.

One of the most desirable situation is the availability of resistant or tolerant cultivars to a given geminivirus disease, as this can provide complete protection. These materials are obtained by conventional breeding methods by introgressing pertinent genes in commercial cultivars usually from wild relative species. Crops for which there are materials with effective resistance to specific begomovirus diseases include cassava (African cassava disease), cotton (cotton leaf curl disease) and tomato (tomato yellow leaf curl disease).

When resistant cultivars are not available, simple control measures can be taken in order to initiate crops with virus-free planting materials, thus reducing the amount of primary inoculum. In the case of vegetable propagated from seeds, whenever possible, transplants should be produced in greenhouses instead of in open fields to protect them from insect vectors. An extreme case of this approach is to protect the crop during the entire season, as it is done when high-value vegetables are grown in greenhouses. For crops propagated from cuttings, as cassava or sweet potato, mother plants should be selected based on absence of symptoms and molecular tests to discard infected plants. Another action to be taken in annual crops is to establish them at the moment when the source of inoculum and the populations of the insect vector are the lowest possible, thus delaying infection and providing protection to young, highly susceptible, plants. In some cases, mandatory host-free periods can be established in a given area. Such host-free periods have been implemented for example in Costa Rica and Brazil to protect tomato crops from begomovirus infections.

Just as vector insects play a key role in the life cycle of geminiviruses, their control is also essential when controlling the diseases that these viruses cause. A first measure, mostly used by farmers in many circumstances, is the use of insecticides to reduce vector populations. Options include systemic insecticides such as the neonicotinoids, contact insecticides, and insect growth regulators. An important limitation to the repeated application of the same active ingredient in a given area is that insect populations with high resistance to various insecticides can readily emerge, as it has been largely documented for certain species of the *B. tabaci* complex. Even though an insect population is susceptible to insecticide treatment, the effect may not be rapid enough to avoid virus transmission, thus limiting the practical effectiveness of this strategy for the control of geminivirus diseases.

An alternative to chemical insect vector control is biological control using natural enemies, mainly parasitoids and predators. For management of whiteflies and begomovirus diseases in protected crops, numerous commercial preparations are available including the parasitoids *Encarsia formosa* and *Eretmocerus eremicus* and the predators *Nesidiocoris tenuis*, *Macrolophus pygmaeus* and *Amblyseius swirskii*.

Two biotechnological approaches have also been evaluated to generate geminivirus-resistant crops, the production of transgenic plants and the most recent strategy of genome editing using the CRISPR-Cas system. Although many examples of transgenic

plants resistant to geminiviruses have been evaluated and proved to be effective, mostly using gene silencing by RNA interference, these plants have not been commercialized due to controversial public acceptance. Although not yet materialized, commercialization of transgenic bean plants resistant to the begomovirus Bean golden mosaic virus have been approved in Brazil. The CRISPR-Cas methodology has been evaluated against geminiviruses by editing the viral genome or host genes encoding factors required for the virus life cycle.

This is an update of J.N. Bragg, H.-S. Lim, A.O. Jackson, Hordeivirus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00426-X](https://doi.org/10.1016/B978-012374410-4.00426-X).

Glossary

Autophagy A conserved eukaryotic mechanism that removes damaged or dysfunctional components.

CRISPR/Cas9 A genome editing tool that enables directly edit the genome by removing, adding or altering sections of the DNA sequence.

Cryo-EM (Cryo-electron microscopy) An electron microscopic technique that involves freezing and applies on protein structure analysis.

PTM (Posttranslational modification) A biochemical modification that occurs to amino acid(s) on a protein after the protein has been translated.

ROS (Reactive oxygen species) Chemically reactive oxygen radicals as well as non-radical derivatives of oxygen.

VIGS (Virus-induced gene silencing) A reverse genetics tools for gene function analysis that uses viral vectors carrying a target gene fragment to produce dsRNA which initiates the silencing of the target gene.

VSR (Viral suppressor of RNA silencing) Viral proteins which can counteract the host silencing-based antiviral process.

Introduction

The genus *Hordeivirus* has been assigned to the family *Virgaviridae*. Hordeiviruses represent a unique genus of serologically related viruses with rigid rods that are composed of 96% protein and 4% RNA. Although members of the genus *Hordeivirus* have similar particle structure, they collectively infect both monocots and dicots and exhibit considerable biological diversity. *Barley stripe mosaic virus* (BSMV), the type member of the genus, can be traced back to ~750 years ago at a site near the Nile River in modern-day Egypt, and the virus has subsequently spread around the world via global movement of seeds. BSMV has been known to cause serious worldwide disease problems in cultivated barley for more than 85 years, and during this time has also been isolated infrequently from wheat and wild oats. Because of the yield losses caused in barley, a number of strains of the virus have been isolated and their biological properties evaluated. The survival of BSMV in nature depends solely on direct plant-to-plant contact and seed transmission; consequently, virus spread can be prevented by planting virus-free seed. The advent of sensitive virus detection methods has permitted seed to be screened prior to planting, thus virus-free seed production has resulted in eradication of the virus in most areas of North America, Europe, and Asia.

Taxonomy and Characteristic

In addition to Barley stripe mosaic virus, three additional species, Poa semilatifolia virus (PSLV), *Lychnis* ringspot virus (LRSV), and Anthoxanthum latent blanching virus (ALBV) have been included in the genus *Hordeivirus* in the Eighth Report of the International Committee on Taxonomy of Viruses (ICTV). This assignment is based on serological relatedness of the coat proteins, genome organization, and sequence relatedness of BSMV, LRSV, and PSLV. The coat proteins of BSMV, LRSV, and PSLV are similar in size, but have different mobilities on polyacrylamide gels and are distantly related serologically. Serology and analyses of coat protein sequences indicate that BSMV and PSLV are more closely related to each other than to LRSV. Serological studies also show that ALBV is closely related to BSMV, and may be a strain of BSMV. However, ALBV has not been investigated by hybridization or sequence analysis to determine whether it is a strain of BSMV or is a distinct virus.

PSLV has been recovered on two occasions from native grasses in widely separated locations within Canada, and from one location in Hungary, throughout North America and Europe, so the virus may be relatively abundant amongst members of the *Poaceae* throughout North America and Europe. LRSV was first isolated from *Lychnis divaricata* seeds imported into the USA, and an additional mild strain of LRSV has been isolated in Hungary. Infectious cDNA clones of LRSV and PSLV have been constructed and used to compare some biological and biochemical properties with BSMV. ALBV has been described only in Great Britain and little is known about its properties. As is the case with BSMV, LRSV is highly seed transmitted, but seed transmission has not been reported for PSLV or ALBV. All of the viruses reach high concentrations in infected plants and are easily transmitted from plant to plant by mechanical contact.

In addition to their limited natural host ranges, numerous experimental hordeivirus hosts have been identified by mechanical inoculation and agro-infiltration of recombinant DNA clones. BSMV has been shown to infect several monocots and a few dicots, and recently, *Brachypodium distachyon*, wild emmer (*Triticum turgidum* var. *dicoccoides*), *Dasyphyrum villosum*, ginger (*Zingiber officinale* and *Z. zerumbet*) have been shown to support BSMV replication. Local lesions on *Chenopodium* species have been used for several

genetic studies of BSMV disease phenotype, and systemic *Nicotiana benthamiana* infections have provided a basis for analyses of virus life cycle and virus-host interactions in dicot hosts. PSLV infects several monocots while LRSV has been shown to infect several experimental dicot hosts, including several *Nicotiana* species and members of the family *Caryophyllaceae*. Reverse genetic systems for BSMV, PSLV, and LRSV have recently resulted in considerable information about biological properties of the viruses and the molecular biology of their infection processes.

Virus Particle Structure

The CP interacts with the genomic RNAs to form short rod-shaped particles and always undergo end-to-end aggregation during extraction *in vitro*. The length of BSMV virions range from about 110–150 nm, similar with LRSV but 20% shorter than PSLV. A cryo-EM structure of BSMV virion suggests that BSMV has an average of 23.2 subunits per helix turn and has two types of virions. A wide virion form has an additional CP per turn compared with the narrow form, and has specific contact differences between the CP subunits. The diameters of the wide and narrow virions are 22.4 and 21.6 nm, respectively, and the corresponding helical parameters are 106 and 111 subunits/period. In addition, the inter-subunit of the narrow virion has two more salt bridges than the wide virion. In agreement with their serological relatedness, the BSMV and PSLV coat protein sequences are more similar to each other than to the CP of LRSV. Although the CP shares several conserved motifs with other rod-shaped viruses, the hordeivirus CPs are closely related to those of members of the fungal-transmitted virus species *Peanut clump virus* (PCV) and *Indian peanut clump virus* (ICPV), but have limited similarity to *Soil-borne wheat mosaic virus* (SBWMV).

Genome Structure and Expression

Hordeiviruses are composed of three genomic (g) RNAs that have been designated α , β , and γ based on hybridization of the viral RNAs. The sizes of the BSMV α , β , and γ gRNAs vary between strains, with the ND18 strain sizes being 3.8, 3.2, and 2.8 kb, respectively. RNAs α and β are similar in size among strains of BSMV, but the sizes and complexity of the γ RNAs vary considerably. The PSLV and LRSV α , β , and γ gRNAs are similar in size (3.9, 3.6, and 3.2 kb, and 3.8, 3.0, and 2.7 kb, respectively) to those of BSMV.

Each of the hordeivirus RNAs has a 7-methylguanosine cap at the 5' terminus, and amongst the gRNAs within a species, the 5' untranslated regions (UTRs) that are necessary for replication have very little sequence similarity. Obvious sequence similarity is not evident among the 5' UTRs of the α and γ RNAs of BSMV, PSLV, and LRSV, but the RNA β components of the three viruses have considerable sequence similarity. The hordeiviruses gRNAs also contain a conserved 3' terminal non-translated sequence that is required for replication. The 3' termini are variable in length between the different viruses, ranging from 184 nt in LRSV to 290 ~ 330 nt in PSLV. The sequences form tRNA-like structures that in BSMV and PSLV are capable of binding tyrosine *in vitro*. Sequence comparisons indicate that the structures are very similar except that the 3'UTRs upstream of the conserved tRNA regions of the PSLV and BSMV RNAs have a large stem loop element and an array of possible pseudoknot stem loop regions that make the 3' UTR longer than that of LRSV. An internal poly(A) sequence of varying length is located directly after the stop codon of the 3' proximal gene of each RNA, and resides immediately upstream of the conserved 3' tRNA termini in the BSMV and LRSV genomes. Intriguingly, the poly(A) sequence is absent in the PSLV genome.

Hordeivirus gRNAs (Fig. 1) encode seven proteins. The replicase protein subunits are encoded by the α and γ gRNAs. RNA α encodes a single protein (α a) that contains methyltransferase and helicase domains that are highly conserved between Sindbis-like viruses. The bicistronic γ RNAs encodes the polymerase (γ a) subunit, which contains the conserved GDD motif found in RNA-dependent RNA polymerase (RdRp) proteins of RNA viruses, plus a 3' encoded cysteine-rich protein (γ b).

RNA β encodes the coat protein in the first open reading frame (ORF), and is followed by a series of overlapping ORFs termed the 'triple gene block' (TGB) that are also present in alexi-, beny-, carla-, fovea-, peclu-, pomo-, and potexviruses. The first ORF of the TGB encodes the TGB1 protein (formerly designated β b). The remaining two TGB ORFs encode the small hydrophobic proteins, TGB2 and TGB3 (formerly called β d and β c, respectively).

The α a, β a (coat protein), and γ a proteins encoded by gRNA α , gRNA β , and gRNA γ , respectively, are translated directly from the gRNAs (Fig. 1). Expression of the TGB proteins is mediated by transcription of two subgenomic (sg) RNAs, designated sgRNA β 1 and sgRNA β 2. TGB1 is translated from sgRNA β 1, and the other overlapping proteins, TGB2 and TGB3, are expressed from sgRNA β 2. Despite sequence predictions, *in vitro* translation assays, and barley protoplasts showing that the TGB2' protein is translated from sgRNA β 2, the TGB2' inactivated mutant has no detectable effects on BSMV infection in *N. benthamiana*. The γ b protein is translated from sgRNA γ . Each of the encoded proteins is expressed at different levels and times during the life cycle, and the three sgRNAs have similar variances in their abundance during replication. High-level constitutive expression of sgRNA γ occurs throughout the replication cycle, but expression of sgRNA β 1 and sgRNA β 2 is temporal. In addition, sgRNA β 1 is considerably more abundant than sgRNA β 2. The three sgRNA promoters have little obvious sequence relatedness; However, the individual BSMV, LRSV, and PSLV sgRNA promoters share a number of blocks of conserved sequence. Pairwise combinations indicate that the BSMV and PSLV promoters have the highest conservation, whereas the LRSV promoters have undergone more divergence. These results and the protein comparisons described below support existing evidence for a common origin of the hordeiviruses and buttress biological evidence suggesting that BSMV and PSLV are more closely related to each other than to LRSV. Additional comparisons of

Fig. 1 The tripartite genome of BSMV and sgRNAs used for expression of the genes encoded by the β and γ RNAs. Each genomic (g) RNA and sub-genomic (sg) RNA contains a 5' cap structure (m^7G) and an internal polyadenylate sequence (A_n) preceding a 238 nt tRNA-like region that terminates with a UAA sequence. The three gRNAs are designated α , β , and γ and contain open reading frames (ORFs) represented by rectangular blocks. RNA α consists of a single ORF (α) that is translated directly from the gRNA. The α protein forms the 'helicase subunit' of the RNA-dependent RNA polymerase (RdRp) and contains characteristic chloroplast transit peptides (cTP), methyltransferase (MT) and helicase (Hel) motif signatures. RNA β encodes the 5' proximal coat protein (CP) and three overlapping triple gene block (TGB) proteins (TGB1, TGB2, and TGB3), that are each required for cell-to-cell movement. The CP ORF is translated directly from gRNA β and the TGB proteins are expressed from two subgenomic (sg) RNAs, sgRNA β 1 and sgRNA β 2, that are illustrated below gRNA β . TGB1 contains two positively charged regions, NoLS and NLS, toward the N-terminus of the protein and a Hel domain, whereas TGB2 and TGB3 are small hydrophobic transmembrane proteins. The bicistronic RNA γ encodes the 5' γ a GDD-containing polymerase protein subunit, and the 3' proximal γ b cysteine-rich pathogenesis protein. The γ a protein is translated directly from gRNA γ and the γ b protein is expressed from sgRNA γ b.

the TGB promoter sequences of several other viruses possessing TGB movement proteins have revealed no strong correlations in sequence or secondary structure between these putative promoter sequences and those of BSMV.

Replication of BSMV gRNAs requires the 5' and 3' terminal regions, but additional internal *cis*-elements are required for replication of each of the RNAs. RNA α replication is *cis*-preferential, with replication appearing to be coupled to translation of a functional α protein. The 117 nt intergenic region separating the β a (coat protein) ORF and the TGB1 ORF has a *cis*-acting function required for replication. In contrast, RNA γ replication is not dependent upon the 42 nt intergenic region separating γ a and γ b, but essential *cis*-acting elements are present in the first 500 nt of the γ a gene.

Function and Relatedness of the Hordeivirus Proteins

Replicase Proteins (α a and γ a)

BSMV gRNAs expressing α a and γ a are able to replicate in protoplasts. The α a and γ a proteins are essential subunits of the RdRp and are members of the tobamo-lineage of supergroup III RdRps. A histidine-tagged γ a protein recovered from infected barley fractionates with the α a protein and the recovered complex exhibits BSMV RNA-specific polymerase activity. Therefore, the α a and γ a proteins constitute the helicase and polymerase subunits of the RdRp complex.

The α a protein contains amino-terminal methyltransferase and carboxy-terminal NTPase/helicase domains. The methyltransferase domain likely functions in capping of the viral RNAs and the DEAD box helicase domain consists of at least six amino acid motifs that are conserved among the RdRps of different groups of RNA viruses. Software predictions show that α a has a chloroplast-targeted transit peptides (cTP) at the amino-terminus, and both subcellular localization assays and immuno-gold labeling experiments demonstrate that BSMV α a is localized on the chloroplast surface. A subcellular localization assay has also shown that LRSV α a has a chloroplast localization signal and targets to the chloroplasts when transiently expressed in *N. benthamiana*.

The γ a RdRp hordeivirus subunits contain a GDD polymerase motif toward their C-termini that is characteristic of the supergroup III polymerases, and this domain falls into the 'tobamo-lineage' among the plant viruses. Phylogenetic comparisons of hordeivirus polymerase subunits reveal more than 75% conservation within the genus and lower levels of conservation extend into members of the genera *Pecluvirus*, *Furovirus*, *Tobravirus* (> 65%), and *Tobamovirus* (> 30%). Sequence comparisons of the NTPase, helicase, and GDD motifs have revealed significant conservation among the polymerase subunits of Sindbis-like viruses (supergroup III). Among the plant

viruses within this group, the conserved domains of BSMV and PSLV are more closely related than those of LRSV, and these sequences also share close relatedness with viruses in the genera *Furovirus* and *Pomovirus*. Lower levels of sequence relatedness are observed when comparisons are extended to the genera *Tobravirus* and *Tobamovirus* and members of the family *Bromoviridae*.

Coat Protein

The coat protein (CP) is translated directly from gRNA β and is the most abundant of the viral proteins in infected plants. The CPs of all hordeiviruses are approximately 22 kDa in size, but exhibit different electrophoretic mobilities.

Studies of BSMV show that the CP is not essential for infectivity of two systemic hosts (barley and *N. benthamiana*) or *Chenopodium* species that form local lesions. An LRSV CP deletion mutant is also dispensable for systemic infection of *N. benthamiana*. Moreover, infections elicited by CP-deficient BSMV mutants appear to be more aggressive, and the phenotype is more severe and protracted in barley and *N. benthamiana* than derivatives expressing the CP. Plants infected with CP deletion mutants have serious mosaic and deformity symptoms in systemically infected leaves and appear to lack the recovery phase of infection that is usually observed in barley and *N. benthamiana* inoculated with BSMV. Molecular analysis also reveal that CP-deficient mutants have higher levels of viral RNA accumulation in barley and *N. benthamiana* than wild type BSMV, which suggests that the CP may affect replication through a feedback mechanism during the late stages of the virus life cycle when RNA replication switches to virion assembly.

TGB Movement Proteins

The hordeiviruses encode Class I TGB proteins that differ in several features from the Class II TGB proteins of *Potato virus X* (PVX) and other viruses of the family *Alphaflexiviridae*. Coordinated actions of each of the three TGB proteins are required for cell-to-cell and systemic movement. The proteins are expressed transiently and simultaneously during the early stages of infection and decline in abundance at later stages of infection.

TGB1

The TGB1 protein, encoded by the 5' proximal TGB gene, is expressed from sgRNA β 1 and accumulates to high levels early in infection. Among the hordeivirus species, the TGB1 proteins range from 50 to 63 kDa in size. These proteins can be distinguished from the ~25 kDa Class II TGB proteins of the *Alphaflexiviridae* by having substantially larger N-terminal domains preceding the helicase domain. The N-terminal half of the hordeivirus TGB1 proteins contains two positively charged regions rich in lysine and arginine residues. The N-terminal region also contains a nuclear localization signal (NLS) and a localization signal (NoLS), both of which are required for nuclear-cytoplasmic trafficking of TGB1 and viral cell-to-cell movement. The C-terminal half of the TGB1 protein contains an NTPase/helicase domain with seven conserved motifs (I, IA, II, III, IV, V, and VI) that are characteristic of superfamily I helicases of alpha-like viruses. The TGB1 NTPase/helicase domain is similar to the helicase domain present in the α a protein and is also essential for BSMV movement. The PSLV TGB1 protein has RNA helicase activity *in vitro* that is dependent on Mg²⁺ and ATP and can unwind RNA duplexes in both 5' - to - 3' and 3' - to - 5' directions. The BSMV and PSLV TGB1 proteins also bind ATP and dATP, and exhibit ATPase activity that maps to motifs I, IA, and II in the helicase domain.

The BSMV TGB1 protein has RNA-binding activity at high ionic strength and exhibits a high binding affinity for both double-stranded (ds) RNAs and single-stranded (ss) RNAs. RNA sequence specificity has not been detected in binding studies, and TGB1 has little detectable affinity for DNA. The TGB1 proteins of both BSMV and PSLV contain multiple RNA-binding regions, and in PSLV, the N-terminal half of TGB1 containing the positively charged regions is able to bind RNA under high-salt conditions, whereas the C-terminal half containing the helicase motif binds RNA only under low-salt conditions.

A BSMV TGB1/RNA ribonucleoprotein (RNP) complex has been purified from infected barley, demonstrating that TGB1 also binds to RNA *in vivo*. In addition, the TGB1 protein also participates in both homologous interactions and TGB3 binding. When GFP-TGB1 is transiently expressed in the absence of TGB2 or TGB3, the TGB1 protein is localized in cytoplasmic membranes. However, when GFP-TGB1 was expressed *in cis* during BSMV infection, fluorescence was evident on opposite sides of the cell wall, suggesting that TGB1 localizes to the plasmodesmata (PD). Due to its RNA-binding activities and presence in an RNP complex recovered from BSMV-infected plants, the TGB1 protein appears to function in formation of movement complexes that are transported to plasmodesmata and to adjacent cells during interactions with TGB2 and TGB3. Additionally, TGB1 interacts directly with a host factor, nucleolar protein fibrillarin (Fib2), and is a key component of a BSMV ribonucleoprotein (RNP) movement complex that functions in cell-to-cell movement.

TGB2 protein

Among the hordeivirus TGB proteins, the TGB2 protein contains the highest amount of sequence similarity within the hordeiviruses, and the degree of sequence similarity extends to the class I TGB2 proteins encoded by PVX and other members of the family *Alphaflexiviridae*. The TGB2 sequence contains two hydrophobic stretches and a conserved hydrophilic region that separates the hydrophobic residues. The hydrophobic regions are predicted to integrate into membranes with a U-shaped topology that directs the termini of the proteins to the cytoplasmic side of the membrane, and the strong conserved central portion of the protein is exposed to the ER lumen.

When expressed alone, the GFP-TGB2 protein is associated with the cortical ER where actin and TGB3 interactions result in dramatically increased filament thickening at the infection front of *N. benthamiana* leaves and motile vesicles resembling Golgi stacks that co-localize to plasmodesmata. However, in BSMV RNA α and RNA γ infections, ectopically expressed GFP-TGB2 proteins associated with chloroplasts, which suggests that TGB2 may have unknown roles in chloroplast infection processes.

TGB3 protein

The TGB3 protein is encoded by the 3' proximal ORF of sgRNA β 2 and is translated by leaky scanning of ribosomes past the TGB2 AUG, which is in a poor context for translation initiation. This mechanism normally produces about a 100:10:1 ratio of TGB1:TGB2:TGB3 during *in vitro* translation. The TGB3 proteins are the least conserved of the TGB proteins, and the class 1 and 2 TGB3 proteins are thought to have a polyphyletic origin, in contrast to the TGB2 proteins that are thought to have originated from a common ancestor.

The N-termini of the approximately 17 kDa TGB3 proteins from each of the hordeivirus species contains a stretch of conserved amino acids that includes one histidine and three cysteine residues. The TGB3 protein has two hydrophobic domains separated by a hydrophilic region that contains a conserved tetrapeptide (QDLN) sequence. The transmembrane regions are predicted to direct the TGB3 termini toward the ER lumen. This topology is quite distinct from that of the class II TGB3 proteins of the alphaflexiviruses, which have only a single membrane-spanning domain that results in localization of the C-terminus on the cytoplasmic side of the ER.

When expressed alone, TGB3 localizes to paired peripheral bodies at the cell wall (CW) that appear to lie on opposite sides of the PD channels connecting adjacent cells. The targeting of PSLV TGB3 to the CW requires the central hydrophilic and the C-terminal trans-membrane regions, whereas the BSMV TGB3 protein requires the five C-terminal residues for PD localization. Furthermore, protein interaction studies demonstrate that TGB3 binds both TGB1 and TGB2, and that TGB3 directs targeting of co-expressed TGB1 and TGB2 to paired peripheral bodies at the CW.

Pathogenesis Protein (γ b)

The 3' proximal ORFs of the hordeivirus γ RNAs encode cysteine-rich γ b proteins that range in size from 16 to 20 kDa. The hordeivirus γ b proteins share some structural similarities, but have little direct amino acid sequence similarity with the cysteine-rich proteins of tob- and carlaviruses. Studies of the BSMV ND18 strain demonstrate that γ b is not strictly required for infectivity in plants, but that it affects pathogenicity and virus accumulation. Extensive mutational analyses of γ b have revealed a number of distinct phenotypes that can ameliorate or exacerbate disease symptoms in barley, *Chenopodium* species, and *N. benthamiana*.

The majority of the cysteine residues in γ b are concentrated in the N-terminal half of the protein. These residues are clustered in two zinc-finger-like motifs, designated C1 and C2. A basic motif (BM) rich in lysine and arginine residues is located between the cysteine-rich regions. The BSMV γ b protein has been expressed and purified from *Escherichia coli* and shown to bind ssRNAs and zinc *in vitro*. The basic motif mediates RNA-binding activity and is involved in replication processes, and the C1, BM, and C2 regions each show independent zinc-binding activity. A coiled-coil domain near the C-terminus of the γ b protein mediates self-interactions that affect pathogenicity.

The hordeivirus γ b protein also has viral suppressor of RNA silencing (VSR) activities that interfere with host RNA silencing mechanisms, and recombinant BSMV mutants that lack γ b protein functions have reduced virulence. *Cis*- or *trans*- rescue with other VSR proteins, such as the *Tomato bushy stunt virus* (TBSV) P19 and Potyviral HC-Pro proteins, provide RNA silencing activities that partially restore BSMV virulence. The coiled-coil region of BSMV γ b is required for RNA silencing suppression, suggesting that homologous interactions of γ b are required for RNA silencing suppressor activity. In addition, individual site-specific mutations within the C1, BM, and C2 region of γ b also affect VSR activity of the protein, which suggests that RNA and metal binding are critical virulence components.

Fluorescence of the BSMV γ b-GFP fusion protein is dispersed throughout the cytoplasm, and subcellular fractionation of infected barley tissue and *N. benthamiana* leaf cells confirms that the protein is located in both the soluble and membrane fractions. In the presence of RNA α and RNA γ , a majority of the γ b proteins are recruited to the chloroplasts by interactions with the α a replication subunit protein. These interactions directly affect the BSMV replication cycle by binding progeny ssRNA, to facilitate enhanced dsRNA unwinding and BSMV replication. In addition, circumstantial evidence suggests that γ b may be involved in multiple steps of BSMV infection.

Cytopathology and Replication

Microscopy studies of BSMV-infected barley indicate that most of the visible changes in leaf appearance can be attributed to the disruption of organelles, most notably in chloroplasts of expanding barley and *N. benthamiana* leaves. Microscopy studies in *N. benthamiana* reveal cytoplasmic invaginations (CI) of the chloroplast outer membrane that contain ~50 nm diameter spherule structures within the invaginations that are characteristic of virus replication vesicles (VRCs) (Fig. 2). Several lines of evidence have confirmed that the BSMV α a replication protein has a major role in initiating chloroplast membrane remodeling to form the VCRs. At early stages of virion assembly, large numbers of virions accumulate in association with the CI's, suggesting that CI's may

provide sites for virion assembly, but at later stages of infection, so many virions are present in the cytoplasm and associated vacuoles that it is difficult to determine specific sites of accumulation.

A model for hordeivirus replication posits that virions are disassembled by host factors in the plant cell, followed by translation of RdRp subunits from RNA α and RNA γ (Fig. 3). The available evidence indicates that the α subunit replication protein localizes to chloroplasts via an N-terminal chloroplast localization signal and induces chloroplasts outer membrane invaginations. The α protein is then posited to recruit gRNAs, the γ subunit, γ b, and relevant host factors to the chloroplasts to facilitate replication. Current evidence suggests that the γ b protein is recruited to the VCRs by interactions with the methyltransferase (MT) hinge-like domain of the α protein. During replication, the γ b protein enhances the helicase activity of the α protein via its N-terminal ssRNA binding activity to facilitate efficient RNA unwinding and replication. Subsequently, progeny vRNAs in the VRCs interact with TGB1 proteins to assemble RNP movement complexes. These complexes participate in movement by interacting with TGB2

Fig. 3 Model of the hordeivirus infection cycle. Hordeivirus transmission from plant to plant occurs via mechanical or pollen transmission, and infections may be subsequently maintained by seed transmission through the embryo to germinating seedlings. Entry during mechanical abrasion is followed quickly by uncoating of gRNAs in the cytoplasm and translation of gRNAs α , β , and γ . Then, the translated α and γ proteins interact with gRNAs to form RNA-Dependent-RNA polymerase complexes that localize at chloroplast outer membranes where membrane invaginations are induced to form nascent VRCs. The RdRp then recruits relevant host factors (HF) to the VRCs to initiate robust gRNA replication. Production of negative- and positive-sense gRNAs results in formation of dsRNA replicative intermediate species. The RdRp also initiates transcription of sgRNAs from internal promoters on negative-strand RNA β and RNA γ to generate sgRNAs that function in translation of proteins encoded by the sgRNAs. The γ b protein, translated by sgRNA γ , functions as a helicase enhancer to facilitate RNA replication and subvert host autophagy processes. During the course of these events, phosphorylated γ b proteins suppress RNA silencing pathways and host cell death responses. The TGB1 protein has a nuclear phase during movement and relies on the importin α/β protein for some aspects of nuclear-cytoplasmic export and trafficking. The exported TGB1 protein interacts with the fibrillarin protein and binds to positive-sense gRNAs to create ribonucleoprotein (RNP) complexes. The TGB2 protein functions in ER/actin membrane thickening at the infection front, and binds to TGB3 proteins that interact with CK2 kinase phosphorylated TGB1-RNP complexes during transport to the plasmodesmata (PD). The TGB3 C-terminal amino acids have a central role in PD recognition and transit of RNP gRNAs complexes to adjacent cells, and the γ b protein may also be involved in some aspects of movement. The TGB2 and 3 proteins also may be recycled by the endocytic pathway to facilitate the movement of additional RNP complexes. As the later stages of infection progress, increasing amounts of CP are translated from gRNA β and encapsidate positive-sense gRNAs at chloroplast encapsidation sites to form progeny virions that accumulate in the cytoplasm.

and TGB3 to elicit actin remodeling that produces dramatically thickened filaments that associate with the endoplasmic reticulum. TGB2 and 3 actin interactions then facilitate transit of RNP complexes to peripheral vesicles and through the PD to adjacent cells. Molecular events involved in virion assembly are currently obscure, but it is likely that the CP has a major role in interacting with nascent gRNAs at CIs during the late stages of replication for virion assembly.

Pathogenesis

Natural mutants in both the non-coding and coding regions of BSMV RNAs have been shown to have strain-specific effects on pathogenesis. For example, the ND18 strain is unable to infect oats, whereas the CV42 strain is pathogenic in this host. ND18 virulence in oats can be engineered by altering a single amino acid in the α a protein, so this phenotype may result from specific associations of α a with a host protein. Some site-specific amino acids of BSMV are potential targets of host resistance genes. Most of the known resistance genes in barley and oats are recessive, but analysis of the inheritance of resistance in *B. distachyon* indicates that a single dominant gene, designated *Barley stripe mosaic virus resistance 1* (*Bsr1*), recognizes an arginine residue at position 390 (R390) and a threonine residue at position 392 (T392) of BSMV_{ND18} TGB1 and elicits the BD3–1 *Bsr1* hypersensitive response, whereas the BSMV_{NW} containing lysines at both positions does not.

Natural variation amongst BSMV strains has also facilitated identification of factors affecting seed transmission. Primary determinants influencing the efficiency of seed transmission reside in RNA γ sequences in the 5' UTR and in the γ b gene. In a fourth case of strain-specific virulence, ND18 is able to systemically infect *N. benthamiana*, whereas the Type strain is able to replicate and move in inoculated leaves, but is unable to invade systemically. Infections with the ND18 and the Type strains also result in

different local lesion phenotypes on *C. amaranticolor*. These aberrant phenotypes appear to be caused by the presence of a short ORF within an amino-terminal 372-nucleotide duplication in the 5' UTR of the Type strain that reduces γ a translation. However, the γ a replicase/host interactions contributing to these distinct movement properties have not been defined molecularly, and differences in the amino acid composition of the γ b proteins may also affect the disease phenotypes.

Advances in understanding pathogenesis have also been obtained by reverse genetic mutations. The results show that γ b is not strictly required for infectivity in plants, but that it has important pathogenicity effects. Individual site-specific mutations within the cysteine-rich region of γ b can also result in a variety of phenotypes ranging from striking white regions to necrotic streaks on systemically infected leaves of barley and *N. benthamiana*. Moreover, plants infected with site-specific γ b mutants have secondary effects that culminate in greatly reduced abundance of viral RNA accumulation. Although the CP is not required for infectivity in barley, *N. benthamiana*, or *Chenopodium* species, infections elicited by CP-deficient BSMV mutants appear to be more aggressive, because recovery is protracted and the symptoms are more severe than in the presence of the CP. These results suggest that in addition to being essential for formation of virions, the coat protein may have a critical role in the kinetics of replication late in infection. Overall, these analyses suggest that complex interactions may affect virulence and disease phenotype, and that the levels of replication may have important effects on movement, host range, and seed transmission.

Molecular genetic studies also suggest substantial specificity amongst genes encoded by BSMV, LRSV and PSLV RNAs, because heterologous strand reassortments of BSMV, LRSV, and PSLV gRNAs, fail to establish systemic infections in plants. However, substitution of the PSLV TGB for the BSMV TGB in RNA β results in systemic infections of *N. benthamiana*, *C. amaranticolor*, and wheat (*Triticum durum*), whereas similar LRSV TGB substitutions failed to establish systemic infections of any of these plants. Interestingly, BSMV infects all 4 hosts tested, whereas PSLV infects only wheat and LRSV infects *N. benthamiana* and *C. amaranticolor*, but not wheat. These results suggest that factors other than the TGB sequences *per se* contribute to host range, but this appears not to be a consequence of γ b because our recent studies show that heterogeneous substitutions of PSLV and LRSV γ b for BSMV γ b do not interfere with the ability of BSMV to infect *N. benthamiana*.

Hordeivirus-Host Interactions

γ b Interference With Host Defenses

RNA silencing pathways

Several lines of evidence indicate that a major function of γ b is to serve as an inhibitor of host defense mechanisms that target RNA replication. A VSR deficient γ b mutant compromises BSMV replication, but the γ b function can be partially complemented by expression of tombusvirus p19 and potyvirus HC-Pro VSRS *in cis* or *in trans*. Similarly, expression of the γ b protein is able to suppress silencing in heterologous virus-induced silencing systems. An agrobacterium-mediated transient silencing assay also provides strong support for a role of γ b in suppression of RNA silencing. In this assay, γ b interferes with silencing of GFP fluorescence induced by expression of dsRNAs. These results thus provide a persuasive argument that a major function of γ b is to counter host innate RNA interference defenses, as well as to assist in helicase unwinding during replication.

Autophagy responses

Autophagy is a conserved defense pathway against abiotic and biotic stresses including virus infection. However, plant virus counter-defense mechanisms that interfere with autophagy to promote viral infection have not been explored extensively. We recently found that BSMV infection suppresses autophagy and that expression of the γ b protein is sufficient to inhibit autophagy. Molecular analyses indicate that γ b interferes with interactions of the autophagy-related protein 7 (ATG7) with ATG8 in a competitive manner and the conversion of ATG8 to ATG8-PE. These findings reveal that the γ b protein subverts autophagy-mediated antiviral defenses by disrupting ATG7-ATG8 interactions to promote BSMV infection, and that ATG7 is a newly discovered target of pathogen effectors in the plant defense and virus counter-defense arms race.

ROS bursts

Reactive oxygen species (ROS) such as hydrogen peroxide (H_2O_2) or superoxide anions (O_2^-) are amongst the earliest cellular responses against pathogen infection. BSMV infection reduces both H_2O_2 and O_2^- elevation by ~ 10 fold in inoculated leaves compared with the empty vector. The γ b protein has a major role in reduction of ROS bursts by interacting directly with glycolate oxidase (GOX), which is localized in peroxisomes and is a key constitutive enzyme in the photorespiration pathway. These results demonstrate that γ b interacts with GOX to suppress peroxisomal ROS production and facilitate virus infection, and contributes to an understanding of roles played by ROS and plant ROS-producing enzymes during viral infection.

Post-Translational Modifications of BSMV Proteins

Post-translational modifications are ubiquitous in eukaryotic cells, and are defined by addition of a covalent group or an enzymatic modification of proteins after translation. Viruses have evolved many strategies to hijack host post-translational modification pathways to maximize their pathogenicity. During BSMV infection, protein kinase CK2 from barley and *N. benthamiana* phosphates the TGB1 protein mainly at Thr-401, and Thr-395 kinase docking sites. The TGB1_{T395A/T401A} mutation compromises BSMV cell-to-cell

movement, and the virus fails to develop systemic infections in barley and *N. benthamiana*. The phosphorylated TGB1 protein interacts more strongly than unphosphorylated TGB1 with the TGB3 protein, and this interaction promotes BSMV cell-to-cell movement. Post-translational modifications also affect γ b functions during BSMV infection. A recent study also indicates that γ b Ser-96 is phosphorylated *in vitro* and *in vivo* by a protein kinase A-like kinase. Non-phosphorylatable γ b substitution mutants (BSMV γ b_{S96A} and γ b_{S96R}) reduced BSMV accumulation and induced necrosis in barley, wheat, and *N. benthamiana*. Phosphorylation of the γ b protein at Ser-96 also enhances VSR activity by promoting 21-bp dsRNA binding activity. These results *in toto* suggest that phosphorylation may affect several aspects of pathogenesis and infection, including movement, cell death, and RNA silencing responses.

Hordeivirus Applications to Cereal Genomic Analyses

Virus-induced gene silencing (VIGS) has provided useful approaches to improve our understanding of the functional genomics of monocots and dicots, and several virus vectors have been developed for this purpose. BSMV has been developed into an effective VIGS vector by modifying sequences downstream of the γ b gene to enable expression of untranslatable foreign inserts. This strategy has been successfully applied to *N. benthamiana*, wheat, barley, and *B. distachyon* by targeting phytoene desaturase (*PDS*), magnesium chelatase subunit H (*ChlH*), and plastid transketolase (*TK*) genes for VIGS. Other BSMV VIGS applications have been developed to downregulate host genes known to be involved in disease resistance, and these have enabled identification of genes required for powdery mildew resistance in barley, and rust resistance in wheat. In addition, high levels of foreign proteins and chimeric proteins such as GFP proteins fused to the C-terminus of the γ b protein have been expressed from BSMV vectors. Heterologous γ b proteins less than 110 amino acids have been expressed during systemic infections, and the fusion proteins can be efficiently and constitutively expressed during infections of *N. benthamiana* and some monocots. These studies indicate that BSMV VIGS provides a powerful and robust system for gene silencing and gene overexpression from BSMV may have numerous applications for genetic analyses of a large number of cereal crops.

Future Perspectives

The broad host range of hordeiviruses and the information accumulated about virus genes involved in replication, movement, and responses to host resistance provides a rich resource for obtaining insight into the mechanics of infection. Considerable efforts have recently focused on BSMV replication and interactions between hordeivirus-encoded proteins and host factors. However, very little is known about the roles of host interactions that facilitate hordeiviruses replication cycles, switch from replication to RNP movement complexes that move across PD and into vascular tissues, or how host resistance pathways interfere with hordeivirus infection. An understanding of events leading to the establishment of replication factories and initiation and regulation of replication cycles requires additional information about the interplay between chloroplasts and cytoplasmic elements during the early stages of infection. An understanding of BSMV-chloroplast interactions may also reveal mechanisms whereby recessive resistance genes employed in agriculture affect BSMV replication. Additional biochemical and cell biological analyses of the TGB-encoded proteins and their interaction proteins could also hone our understanding of the cell-to-cell and vascular movement events that permit systemic hordeivirus infections, and how hordeiviruses invade vegetative tissue, seed, and pollen. Such investigations may also provide insights into global aspects of the subcellular transport network, and functions of organelles and PD functions in plant development.

New genome-editing techniques like CRISPR/Cas9 have developed rapidly over the past decade, and the use of hordeiviruses for novel applications of these techniques will accelerate future genomics methods. Hence, we envision that more sophisticated analyses of host genes, cellular interactions, and the ability to modulate their expression will accelerate the pace of future hordeivirus research findings.

Glossary

Certification Program Is a comprehensive process established and authorized by a state or other governmental entity for the production of plants free of regulated pests and diseases. The regulations for each program define the program participation, plant production, plant identification and labeling, and quality assurance requirements.

ELISA An acronym for Enzyme-Linked Immuno Sorbent Assay, which is a serological test in which antibodies are used to detect plant viruses.

Foundation Block A foundation block is a group of plants that have been tested for viruses or other diseases and are maintained in isolation under conditions that prevent (re) infection. These blocks are considered Generation 1 (G1) stock within the meaning of the 'Generation level' concept recommended by the NAPPO Guidelines.

Heat therapy Is a method used to eliminate viruses in which plants are grown at 37°C–40°C for 4–6 weeks. This is used in combination with meristem tip culture for efficient elimination of most plant viruses.

Horizontal Transmission Transmission of a pathogen to individuals within the same generation. For pollen-borne plant viruses, this is virus movement from the pollen grain

to maternal tissue during the pollination process resulting in the infection of the pollinated plant.

Meristem tip-culture The process of removing pieces of plant 0.5 mm or less in length, consisting of a meristem and a few leaf primordia that is grown in vitro with the goal of generating a plant free of plant viruses.

Pollen-borne Carried on or in the pollen, plant viruses can be carried on the exterior of the pollen or internally in the pollen grain.

Polymerase Chain Reaction Is a laboratory detection technique for plant pathogens that amplifies a segment of DNA or RNA from the target organism (for example, a virus) many times by using short segments of DNA (primer) that are complimentary to the target nucleic acid. For RNA targets, reverse transcription is required to convert the RNA to DNA that is then used in PCR.

Tissue Culture The cultivation of plants (cells, tissues, or organs) under aseptic conditions in a synthetic medium in vitro.

Vertical Transmission Transmission of a pathogen from one generation to the next, for plant viruses this is the result of seed transmission.

Introduction

Until recently, Raspberry bushy dwarf virus (RBDV) was the sole recognized member of the genus *Idaeovirus*. More recently, Privet leaf blotch associated virus (PrLBaV) has been listed as a member of the genus. A novel virus from blackcurrant, Blackcurrant leaf chlorosis associated virus (BCLCaV), or Blackcurrant idaeovirus (BCIV) has been described by two groups (the acronym BCLCaV will be used here), which is phylogenetically most similar to PrLBaV and RBDV. A third virus, Japanese holly fern mottle virus has similarities in the RNA1 to that of RBDV, but its RNA2 is quite distinct from the other three viruses. A partially sequenced virus from citrus showed significant similarities to the coat protein of RBDV, but complete sequence information is lacking. The initial isolation of RBDV was from plants that exhibited stunting and proliferation, thus the name Raspberry bushy dwarf virus. RBDV was initially isolated from red raspberry by mechanical transmission from symptomatic plants to herbaceous hosts. It was shown later that these plants were coinfecting with Black raspberry necrosis virus and that RBDV in single infections did not cause the 'bushy dwarf' symptoms. However, in single infections, RBDV does induce

crumbly fruit in many cultivars of raspberry and in some cases leaf chlorosis. The virus genus name is from the species of the host (*Rubus idaeus*).

RBDV is serologically indistinguishable from Loganberry degeneration virus and synonymous with Raspberry yellows virus. It is also probably the same as Raspberry line pattern virus reported from Poland. Antisera has not been prepared to the other idaeoviruses. Studies on the molecular biology of RBDV have shown it to possess a novel combination of properties and was assigned as the sole known member in the genus *Idaeovirus*. Though RBDV and the other idaeoviruses have a bipartite genome, they are most similar to the ilarviruses that have tripartite genomes in the family *Bromoviridae*.

Geographical Distribution

RBDV probably occurs wherever red raspberry (*R. idaeus*, *R. strigosus*), black raspberry (*R. occidentalis*), or blackberry (*R. fruticosus*), are grown. The virus has been reported from Australasia, China, Eastern and Western Europe, North and South America, South Africa, and the former Soviet Union. Three strains of RBDV have been characterized based on serological or biological properties. The common or Scottish (S) isolates have been identified in most countries where raspberries are grown. The black raspberry (B) isolate from a North American black raspberry, *R. occidentalis* are serologically distinct from the S isolates. However, more data are needed to determine whether B isolates are restricted to *R. occidentalis*, or representative of isolates from North America, and whether S isolates can occur in *R. occidentalis* in nature. B isolates have only been found in North America in native *Rubus*. A third strain (RB) for resistance breaking, has limited distribution in Europe and was identified in North America for the first time in 2016. These isolates are indistinguishable from S isolates, except that they are able to infect cultivars that are resistant to the S isolates. A fourth strain has been partially characterized from *R. multibracteatus* collected in China, which has 23 aa substitutions in the coat protein (CP) when compared to the B isolate and is the most divergent isolate of RBDV reported to date. It is also distinguishable from D, S, and RB isolates using monoclonal antibodies. A fifth strain has been reported from grapevines in Slovenia and Hungary, which forms a separate cluster from the isolates from *Rubus* species, and can also be distinguished using monoclonal antibodies.

BCLCaV and BCIV were identified using high throughput sequencing from dsRNA purified from symptomatic plants. The distribution and population structure of the virus have not been studied. The virus isolates were from two different blackcurrant cultivars, 'Belaruskaya Slodkaya' held in the *Ribes* germplasm collection at the USDA-ARS National Clonal Germplasm Repository in Corvallis, Oregon, and 'Baldwin' from British Columbia, Canada. In both cases the plants exhibited a general chlorosis symptom. PrLBaV was identified using high throughput sequencing of small RNAs purified from privet (*Ligustrum* spp.) plants exhibiting yellow mosaic symptoms. Infectious chlorosis of privet, variegation of privet, mosaic of ligustrum are considered synonyms of yellow mosaic of privet. In parallel experiments with symptomless privet, the virus was not detected. Additionally, none of the other viruses reported to infect privet were detected in these experiments. There was no mention if there were any other viruses detected in the study that had not been previously reported in privet. The disease has been reported to be widespread in Europe based on symptoms, though it is not known if the multiple reports refer to the same disease or if there are multiple causal agents involved.

Natural and Experimental Transmission

In red raspberry and black raspberry, RBDV is readily transmitted to progeny seedlings via either the pollen or the ovule of infected plants and transmission is greatest when both parents are infected. If raspberry plants were deflowered they did not become infected when adjacent flowering plants of the same cultivar did become infected. Therefore, the flower is believed the route for natural transmission of the virus. Healthy plants can be infected after the first flowering season when planted close to virus sources. The rate of virus spread horizontally in the field varies greatly by cultivar. Horizontal transmission occurs as pollen tubes penetrate the stigma and virus is able to move into the stigmatic tissue, and from there move systemically to infect the plant. This transmission has been documented using pollen from RBDV infected *Rubus* to infect healthy *Rubus* plants. It was also shown that transmission to the maternal tissue requires pollen tube growth into the stigma, but does not require fertilization. Pollen from RBDV infected raspberry placed on stigmas of *Torenia fournieri* resulted in horizontal transmission of RBDV to the maternal tissue if the pollen tube penetrated the stigma. If the pollen was inactivated and not able to grow into the stigma transmission did not occur. Thus, horizontal transmission via infected pollen can occur between sexually incompatible species. RBDV is transmitted easily from *Rubus* by grafting to susceptible *Rubus* species and cultivars. However, graft-inoculated plants may need to go through a dormant season before the virus becomes fully systemic. RBDV is also transmissible from infected *Rubus* to herbaceous test plants by mechanical inoculation of sap extracts in aqueous solutions of either 2% nicotine or in 0.05 M phosphate buffer containing 1% polyvinyl pyrrolidone (PVP) (mol. wt. 6000–40,000 Da). Mechanical transmission from RBDV-infected herbaceous plants to susceptible red raspberry cultivars is possible, but with great difficulty. BCLCaV is graft transmissible to other blackcurrants and PrLBaV is graft transmissible to symptomless privet plants. In both cases, limited work on graft transmission has been reported, so symptoms in different cultivars or species is unknown. BCLCaV was transmitted mechanically to *Nicotiana benthamiana* and *N. occidentalis*. There are no reports of transmission of PrLBaV to herbaceous hosts.

Martin.

Disease Symptoms and Effects

Naturally Infected Plants

In nature, RBDV occurs in wild and cultivated *Rubus* species and cultivars. In single infections RBDV is often symptomless in raspberry and blackberry plants depending on cultivar. However, in sensitive raspberry cultivars and under certain environmental conditions, it can induce chlorosis. This disease is characterized by an initial yellowing of the main or minor veins of the lower leaves that can progress to affect the entire leaf (Figs. 1(A) and (B)). Some raspberry cultivars may also develop chlorotic/yellow rings or line patterns in leaves. RBDV infection also causes 'crumbly fruit' in some raspberry cultivars (Fig. 1). This condition arises from the abortion of some drupelets and the uneven development of others and frequently results in an abnormally shaped fruit, which, on picking, may disintegrate into individual drupelets or drupelet clusters. The same disease syndrome can be induced by other unrelated causes, such as poor pollination conditions, infection with other viruses, or genetic aberrations. Chlorosis and crumbly fruit is also observed in blackberry, but usually when RBDV is present in combination with other viruses (Fig. 1(C)–(F)). Additional symptoms have been attributed to RB isolates. In field studies an association was reported between infection with RBDV-RB and premature defoliation of fruiting canes, decreased vigor, leaf curling, necrosis, and death of laterals, and increased winter kill in some red raspberry cultivars that are immune to S isolates.

In commercial fields, RBDV rarely occurs in single infections. The virus name comes from symptoms in a plant that was co-infected with RBDV and Black raspberry necrosis virus. In single infections RBDV does not cause bushiness or dwarfing symptoms. In mixed infections with Raspberry leaf mottle virus the titer of RBDV in 'Meeker' red raspberry was increased approximately 400-fold over the titer of RBDV in single infections. In mixed infections of RBDV with Raspberry leaf mottle virus or Raspberry latent virus, raspberry plants growth was significantly reduced during the establishment year compared to plants infected singly with RBDV. The mixed infections also resulted in smaller fruit, more severe crumbliness of the fruit and lower yields, than in plants singly infected with RBDV in the first two fruiting years.

RBDV was detected in cultivars of white-fruited and red-fruited grapevines (*Vitis vinifera*) in Slovenia and Hungary. RBDV infected 'Laški Rizling' exhibited line pattern and mild leaf yellowing. In most cultivars RBDV infections were symptomless. RBDV is reported to be widespread in grapevines in Slovenia. Of 390 seedlings grown from seed collected from RBDV infected cv. Laška Rizling, all tested negative for RBDV, suggesting a very low levels or no seed transmission in grapevines. It would be curious to examine horizontal transmission in grapevines using pollen from infected plants. RBDV isolates from grapevine spread systemically in *Chenopodium murale*, which has not been observed with isolates from *Rubus* spp.

Fig. 2 Electron micrograph of a purified preparation of RBDV Particles stained with uranyl acetate. Scale=100 nm. Photographs courtesy of R.R. Martin.

PrLBaV was sequenced from plants exhibiting cream colored blotches, some ringspots, leaves with coalesced blotches leading to almost completely cream colored leaves and in some cases necrotic spots within the cream colored blotches. There was not any testing for the PrLBaV in a large number of symptomatic and asymptomatic plants to document an association between the symptoms and the presence of the virus. BCIV was sequenced from blackcurrant 'Belaruskaya Slodkaya' and BCLCaV was sequenced from blackcurrant 'Baldwin' both exhibiting a general chlorosis of the leaves.

Experimentally Infected Plants

RBDV has been transmitted by graft inoculation from *Rubus* to perennial plants in other genera. It infected *Fragaria vesca* and *Prunus mahaleb* seedlings without any symptoms, and induced pronounced chlorotic vein-banding and line patterns in *Cydonia oblonga* cv. C7-1. RBDV has a moderately wide host range in herbaceous test plants infecting over 50 plant species in 12 families of dicots. The idaeovirus from blackcurrants has been transmitted mechanically to *Nicotiana occidentalis* and *N. benthamiana*. There is no information on mechanical transmission of PrLBaV to herbaceous hosts.

Virion Structure

Chenopodium quinoa is the preferred propagation host for RBDV. Purified virus particles are about 33 nm in diameter, and appear quasi-isometric because they tend to collapse and deform on the electron microscope grid (Fig. 2). They appear more spherical in shape when fixed with formaldehyde. Particle preparations have A260/A280 of 1.62, suggesting that RBDV particles contain about 24% RNA. Purified preparations of RBDV particles typically yield a single major protein estimated by polyacrylamide gel electrophoresis to have a molecular weight of ca. 30 kDa. The particles contain three species of single-stranded RNA (ssRNA) of approximately 5.5 kb (RNA1), 2.2 kb (RNA2), and 1.0 kb (RNA3). RNA3 is a sub-genomic of RNA2 (Fig. 3). The particles are unstable and readily disrupt in the presence of 0.01% sodium dodecyl sulfate, indicating that they are stabilized by protein-RNA interactions.

Genome

The complete nucleotide sequences have been determined for the two genomic RNAs (RNA1 and RNA2) of RBDV isolates S and RB, BCLCaV, and PrLBaV. The genome organization of idaeoviruses is shown in Fig. 3, at this time the 12 kDa putative ORF has only been predicted in RBDV. RNA1 of RBDV (R15 strain), PrLBaV and BCLCaV are 5,449, 5377, and 5349 nt long, respectively. RNA1 codes for a multi-functional protein of ~19 kDa, which contains the methyl-transferase (MTR), helicase (HEL), and RNA-dependent RNA polymerase (RdRp) domains. RNA2 of RBDV (R15 strain), PrLBaV, and BCLCaV are 2,231, 2348, and 2280 nt long, respectively. RNA 2 codes for two proteins, a putative movement protein (MP) and a coat protein (CP) with a molecular masses of about ~39 kDa and ~30 kDa, respectively. The CP of RBDV is expressed via a sub-genomic RNA (RNA3, 946 nt), and this is likely the case for PrLBaV and BCLCaV. This predicted size corresponds to that of protein obtained from purified virus particles and that of the main polypeptide made by in vitro translation of RNA3. Fig. 4 shows phylogenetic relationship among the idaeoviruses and two closely related viruses.

RNA1 also contains a small ORF in a different translation frame that overlaps with the 190 kDa protein, which if expressed could code for a 12 kDa protein. The position of this ORF corresponds to that of the 2b gene in the tripartite genome of Cucumber

Fig. 3 Schematic showing the genome organization of RBDV. RNA molecules are represented by solid lines, the yellow blocks show the open reading frames (ORFs). The relative positions of the functional domains of the polyprotein encoded by RNA1 are MET (methyl-transferase), HEL (helicase) and RdRp (RNA-dependent RNA polymerase), RNA2 codes for the MP (movement protein), and RNA 3, a sub-genomic of RNA 2 codes for the CP (coat protein). PrLBaV and BCLCaV have similar organizations but lack the 12K putative open reading frame.

Fig. 4 Phylogenetic relationship of the idaeoviruses Raspberry bushy dwarf virus (RBDV), Privet leaf blotch associated virus (PrLBaV) and Blackcurrant leaf chlorosis associated virus (BCLCaV), the Japanese holly fern mottle virus (JHFMov) is also included in the polymerase protein since its RNA1 resembles those of idaeoviruses, and Blackberry chlorotic ringspot virus (BCRV), since idaeoviruses have nearest affinities to ilarviruses. Phylogenetic analysis was performed using the coat proteins (a), putative movement proteins (b) and polymerase proteins (c), the BCRV was not included in the polymerase phylogeny due to the multiple functional domains on two RNAs. The trees were generated by the maximum-likelihood PhyML 3.0, using the default parameters. Branch lengths are proportional to genetic distances between sequences and the scale represents substitutions per amino acid site. RBDV, red raspberry isolate (NC_003739, NC-003740); RBDV-Vitis, grapevine isolate (EU796086); RBDV-R.multi, *Rubus multibracteatus* isolate (DQ120126); BCLCaV-Can, Canadian isolate (KX838923, KX838924); BCLCaV-OR, NCGR isolate (KY399998, KY399999); PrLBaV (NC_031341, NC_031342); JHFMov, (FJ907327); and BCRV (NC_011554).

mosaic virus (CMV) that encodes a 10 kDa polypeptide and overlaps the C-terminal 69 codons of ORF 2a that encodes the RNA polymerase protein. The CMV 2b protein is important in long distance systemic movement and the suppression of post-transcriptional gene silencing, but it is not necessary for infectivity. However, experiments failed to demonstrate the activity of the 12 kDa RBDV protein in suppressing post-translational gene silencing. There is a report of RNA1 of RBDV replicating and moving systemic in the absence of RNA2, which suggests the expression of ORF 1a if it serves a long distance movement function similar to that of ORF 2a in CMV.

There are similarities among the 5'- or 3' terminal non-coding sequences of each of the genomic RNA species of RBDV, PrLBaV and BCLCaV. The 5' termini of both RNAs of the three viruses start with the same four nt 5'-AUAU-3'. The 3' terminal regions for RNA1 and RNA2 of each virus share 5-AACCCC-3', with BCLCaV having an extra C residue. Additionally, the 3' termini of RNA1 and RNA2 of each of the three viruses form four similar stem-loop structures. BCLCaV lacks the putative 12 kDa ORF on RNA1,

An isolate of RBDV from *Rubus glaucus* in Ecuador and the BCLCaV from Canada each had a concatenated form of RNA2 that contained an inverted CP gene. The RBDV isolate was cloned and sequenced from a dsRNA template using standard DOP-PCR and Sanger sequencing combined with RACE to obtain the terminal sequences. The dsRNA pattern on an agarose gel showed an unexpected band of about 3.2 kbp. The BCLCaV was sequenced using high throughput sequencing from a dsRNA template. The presence of this unusual RNA in two idaeoviruses suggest that there may be some secondary structure that leads to a rare formation of overhanging sequence that can be transcribed to yield this inverted repeat. In the case of RBDV it was found in a single plant,

Table 1 List of members of the genus *Idaeovirus* (top table). Percent amino acid identity between coat proteins and movement proteins sequences of Raspberry bushy dwarf virus (RBDV), Privet leaf blotch associated virus (PrLBaV), and Blackcurrant leaf chlorosis associated virus (BCLCaV) (bottom table)

Species names	Acronym	RNA1 accession #	RNA2 accession #
Raspberry bushy dwarf virus	RBDV	NC_003739	NC_003740
Privet leaf blotch associated virus	PrLBaV	NC_031341	NC_031342
Blackcurrant leaf chlorosis associated virus	BCLCaV	NC_034408	NC_034390
Tentative members			
Japanese holly fern mottle virus	JHFMoV	NC_013133	NC_013134
Virus	Coat Protein	Movement Protein	
	RBDV	PrLBaV	BCLCaV
RBDV	100	26	23
PrLBaV		100	61
BCLCaV			100

suggesting it may be maintained in vegetatively propagated material, but not encapsidated and therefore not pollen transmitted. It is not known if this is a common occurrence with BCLCaV since there are only two sources that have been sequenced.

Viral Proteins

The Coat Protein

The CPs of the idaeoviruses show no striking similarities with the CPs of other virus genera. An alternative to this sequence-based alignment program is to use secondary structure predictions to produce an alignment. This type of prediction with the RBDV CP predicted a long N-terminal sequence containing two α -helices and followed by a region containing eight β -sheets. If correct, this arrangement would resemble that of the CPs of many viruses that have isometric particles. The N-terminal parts of the CPs of RBDV and of viruses in the family *Bromoviridae* are relatively rich in basic aa, which are thought to be internal in virus particles and to be involved RNA encapsidation. The CPs of the ilarviruses and Alfalfa mosaic virus (AMV) are involved in 'genome activation' and required for virus replication. This phenomenon has also been reported for RBDV, where combining infectious clones of RNA1 and RNA2 gave very low level of infectivity but the addition of RNA3 greatly increased virus replication. With the ilarviruses and AMV addition of CP without adding the sub-genomic for the CP also was very effective at enhancing replication. RNA-binding domains have been shown to play a role in genome activation. In recent analyses using BindN several putative RNA-binding domains were identified in the CP of PrLBaV and similar domains were predicted in the CP of RBDV, though their involvement in genome activation has not been documented (Table 1).

The Movement Protein

RNA2 of RBDV corresponds in size and gene content to RNA3 of viruses in the family *Bromoviridae*. The ORF for the 39 kDa protein therefore corresponds in position to the ORF for the putative MP of members of the *Bromoviridae*. A limited sequence identity was detected in multiple alignment tests between the 39 kDa protein and the putative or actual MPs of several viruses. In further alignment tests of this sort, Mushegian and Koonin have detected a match between part of the 39 kDa protein sequence and a motif conserved in the MPs of some other viruses, such as Red clover necrotic mosaic virus (*Tombusviridae* family, *Dianthovirus* genus) and Soil-borne wheat mosaic virus (*Virgaviridae* family, *Furovirus* genus). These proteins were proposed to belong to a '30 kDa superfamily' of MPs. With PrLBaV the localization of the putative MP (38 kDa) in planta was studied by fusing green fluorescent protein (GFP) to its C-terminus. This fused protein was agro-infiltrated into leaves of *N. benthamiana*. When examined using confocal laser microscopy the GFP was accumulated at the plasmodesmata, which has been observed for other MPs. This provides strong evidence that the 38–39 kDa proteins coded by RNA2 are indeed MPs of the idaeoviruses and involved in virus trafficking.

The Replicase Protein

The sequence of the 190 kDa protein has similarities with replicase proteins of viruses in the Alphavirus superfamily. PFAM analysis identified three conserved domains in the predicted protein of the three idaeoviruses (RBDV, PrLBaV, and BCLCaV) coded by ORF1. The viral methyltransferases (MTR) belong to PF01660, which if found throughout the Alphavirus superfamily. The viral helicases (HEL) belong to PF01443 and the RdRp belong to PF00978. There was homology between parts of the idaeovirus replicase proteins and parts of the 183 kDa protein of Tobacco mosaic virus, but they showed greater similarity with the 90 kDa

protein (RdRp) of AMV (encoded by RNA2), and 125 kDa protein (HEL and MET), which are encoded by RNA1 of AMV. RBDV RNA1 therefore corresponds in size and gene functions to RNA1 plus RNA2 of the tripartite viruses in the family *Bromoviridae*.

Diagnosis and Detection

In *Rubus*, RBDV may induce yellowing, line patterns, or crumbly fruit, but such symptoms are unreliable for diagnosis because they may be due to infection with other disease agents, poor pollination, environmental conditions or poor nutrient management. Also, with many cultivars of raspberry (red and black) and blackberry RBDV is often asymptomatic. Detection and diagnosis therefore depend on bioassays, serological tests and/or reverse transcription PCR assays. RBDV can be detected reliably by ELISA. Many isolates of RBDV are readily detected by mechanical transmission to *C. quinoa* test plants, but this is most effective early in the season and is not as reliable as serological or RT-PCR assays. As the distribution of RBDV in individual *Rubus* plants can be erratic, leaves/leaflets for mechanical transmission or ELISA should be taken and pooled from at least three different nodes. For mechanical transmission newly emerging leaves should be used. For ELISA and RT-PCR, the youngest but fully expanded leaves are the optimal tissue for testing.

Serological Testing

Polyclonal antisera raised to S isolates have a moderate titer of ca. 1/512 in gel double diffusion tests. In agarose gel double-diffusion serological tests spur formation was used to document serological differences between S isolates from B isolates. Monoclonal antibodies to RBDV were able to distinguish three different epitopes of a Canadian isolate of RBDV. Each of the three monoclonal antibodies reacted with all isolates of RBDV from raspberry and blackberry. One of the monoclonal antibodies did not react with the isolates from grape or from *Rubus multibracteatus*. These monoclonal antibodies reacted in double antibody sandwich ELISA (DAS-ELISA) with all tested isolates from red raspberry, including B, S, and RB isolates. They are usually used in combination with a polyclonal antibody for trapping the virus onto the plate, the monoclonal antibodies as the second antibody after the virus has been trapped, and then followed with a goat anti-mouse conjugated antibody. This combination of antibodies are available commercially from several companies and can be used to detect RBDV with minimal equipment. There are not antibodies available for PrLBaV or BCLCaV, so testing for these two viruses is limited to biological assays or RT-PCR.

Reverse Transcriptase – PCR (RT-PCR)

There are more than 75 partial or full sequences of RBDV in GenBank, which is useful for designing detection primers that can capture the diversity of the virus. Detection primers have been designed for end-point RT-PCR and for quantitative RT-PCR. For most applications end-point PCR is used. Also, primers have been designed specific for RNA1 and for RNA2. There has been a report of RBDV RNA1 replicating and spreading systemic in raspberry plants. In this case, the ELISA tests and the end-point RT-PCR based on RNA2 sequences were negative, while the RT-PCR based on RNA1 was positive. It is not known if this is a common occurrence or was a rare event, but care should be taken to include some testing with primers specific for RNA1.

Therapy

Unlike many other viruses infecting *Rubus*, RBDV is not readily eradicated from *Rubus* plants by meristem tip-culture alone. However, heat treatment for several weeks at 36°C followed by meristem tip-culture can be used to eliminate RBDV from infected plants. Even with this combination, virus elimination of RBDV can be challenging. Cryotherapy has been used successfully to eliminate RBDV from raspberry, but again it was not very efficient. Chemotherapy combined with thermal therapy and meristem tip culture has shown some success in eliminating RBDV. RBDV appears to move very readily cell-to-cell and therefore can move into the meristematic dome more efficiently than most viruses.

Prevention and Control

The most important component of virus control in vegetatively propagated crops is to start with virus-tested planting stocks. This requires a clean plant production system. Such a system includes: (1) A facility to produce clean plants, hold the top-tier or G1 plants generally under protected culture (screenhouses to minimize vectors) or in long-term tissue culture at 4°C (**Fig. 5**), and that can retest G1 plants on a regular schedule to ensure they remain clean; (2) A certification scheme that performs audit testing and ensures best management practices are followed during the multiple stages of increase (G2 and G3 blocks) required between the G1 (Foundation Block) and the certified plants sold to growers, (3) Increase blocks that are monitored by the certifying agency and tested for viruses and other targeted pathogens as outlined in the certification standard; (4) A system to track the certified plants under the certification scheme so that disease issues can be traced-back or traced-forward as needed.

Fig. 5 Plants of 'Columbia Star' blackberry in gas permeable sealed bags. These plants can be held at 4°C for up to three years without any maintenance or risk of reinfection. Photographs courtesy of R.R. Martin.

Because RBDV is transmitted in association with infected pollen, the only methods of controlling it in crops are to grow resistant cultivars, or to plant healthy susceptible cultivars in isolation from possible sources of infection. If the virus is present in native *Rubus* spp., isolation from infected sources can be challenging in many growing regions. All black raspberry, blackberry, and blackberry/raspberry hybrids tested were susceptible to the S strains of RBDV. Many red raspberry cultivars are resistant, possibly immune, to S isolates (the most widespread isolates worldwide). This resistance is conferred by the presence of a single dominant gene, *Bu*. All *Bu*-containing cultivars are susceptible by grafting with RB isolates, though the cultivars, 'Heritage', 'Haida', 'Rannaya Sladkaya' were difficult to infect and did not become infected when exposed to the RB isolates under field conditions. There are cultivars that show 'field resistance' and are slower to become infected in the field to either the S or RB isolates. In some cases, cultivars that are susceptible to grafting infection with the S isolates remained RBDV-free in the field up to 20 years, even under conditions where adjacent plantings were nearly 100% infected after 5 years. The mechanism for this has not been studied, but if high fruit quality can be combined with slow to become infected, such cultivars could have a place in production systems. Breeding for field resistance to the RB strain may be a more realistic goal since resistance to this strain has not been identified. RBDV susceptibility has resulted in some cultivars with excellent fruit quality to be abandoned by growers.

Studies on this form of resistance indicated that its mode of inheritance was complex but seemed to depend on the presence of gene *Bu*, together with a second resistance component whose inheritance was probably multigenic. In field studies, some raspberry cultivars, including some that do not contain gene *Bu*, are more resistant than others to natural infection with RB isolates.

'Meeker' red raspberry has been developed with resistance to RBDV that makes use of RNAi. The plants were free of RBDV when challenged in the field for six years under extreme disease pressure when all 202 control 'Meeker' plants in the same test plots were infected after three years in the field. The resistance was stable and effective against graft inoculations that were repeated three times and the transgenic raspberry produced fruit of quality indistinguishable from wild-type 'Meeker'. Though the resistance is effective, the plants are on hold and applications for approval for human consumption to the Food and Drug Administration in the U.S. have not been made, pending a change in public perception on the use of this technology. Additionally, there has been 20 years of breeding since these transgenic lines were developed, and the standard for fruit quality and yield has surpassed that of 'Meeker'.

Relationships With Other Viruses

Idaeoviruses resemble viruses in the genus *Ilarvirus*, family *Bromoviridae* in having quasi-spherical particles that are easily distorted in preparations viewed in an electron microscope. Also, they are transmitted vertically and horizontally in association with pollen as are the ilarviruses. RNA1 of idaeoviruses contains the HEL, MET, and RdRp functions, while in the ilarviruses, RNA1 contains the HEL function and RNA2 contains the MET and RdRp functional domains. RNA2 of idaeoviruses resemble RNA3 of ilarviruses in the arrangement and sizes of its encoded gene products, and the generation of a 3' terminal sub-genomic RNA (sgRNA). RBDV is serologically unrelated to all recognized ilarviruses tested. Also, RBDV differs from ilarviruses in the sedimentation behavior of

its particles, in the number and sizes of its RNA molecules, and in having a bipartite genome. Taken together, these properties distinguish idaeoviruses from all other well-characterized viruses and support their status as a separate genus. The genus *Idaeovirus* has not been assigned to a family, but has many molecular properties in common with members in the family *Bromoviridae*, the major difference being that the multi-functional replicase protein of idaeoviruses is coded one RNA whereas in the family *Bromoviridae* these functional domains are coded by two RNAs. The idaeoviruses have bipartite genomes whereas the six genera in the *Bromoviridae* have tripartite genomes.

Glossary

Bicistronic A viral RNA that encodes two genes which are often separated by a non-coding intergenic region.

Cross protection It describes a phenomenon in that an initial infection of a host plant with a mild strain of a virus induces resistance in that plant to the infection of another, closely related virus potentially protecting the plant from disease caused by a more virulent isolate.

Genome activation Iilarviral genomic RNAs alone are unable to establish infection in plants, unless the coat protein is present. This function of the coat protein is termed genome activation and is specific for ilarviruses and closely related alfamoviruses. The event is triggered by binding of the coat protein RNA binding domain to the 3' terminus of genomic RNA.

RNA silencing A fundamental, evolutionarily conserved and sequence-specific mechanism that is triggered by double-stranded RNA and regulates gene expression in

eukaryotes. It is a primary antiviral defense mechanism in plants and other living organisms.

RNA silencing suppressor A countermeasure to RNA silencing, often a protein encoded by a virus which interrupts a single, or multiple steps in the RNA silencing pathway such as binding to small interfering RNA and thereby preventing their incorporation into the RNA induced silencing complex.

Sub-genomic RNA A segment of RNA generated from a genomic RNA via an international promoter that has the same 3' end as the genomic RNA, but has a deletion at the 5' end. The sub-genomic RNA makes it possible to efficiently translate the downstream open reading frame of the genomic RNA.

Tripartite genome A viral genome consisting of three genomic fragments, which are encapsidated into three separate virions.

Introduction

Iilarviruses are a group of isometric and labile viruses that are distributed worldwide and infect many agriculturally relevant herbaceous and woody hosts including fruit trees, vegetables, and ornamentals. For long time, the economic importance of ilarviruses has been underestimated as they are often considered as latent pathogens, particularly when they infect fruit trees. Since 1990s, a large number of ilarviruses have been molecularly identified, and this group of viruses has received more and more attention. In this article, we briefly discuss the classification, virion structure, genomic organization, and infection cycle of ilarviruses, summarize the current knowledge of their replication mechanisms and transmission modes, highlight the control strategies, viral symptoms and pathogenesis of the viruses, and finally introduce diagnosis of ilarviruses.

Table 1 A list of recognized species in the genus *Iilarvirus*, family *Bromoviridae*

Subgroup	Species	Acronym	GenBank accessions
Subgroup 1	<i>Ageratum latent virus</i>	ALV	JX463341
	<i>Blackberry chlorotic ringspot virus</i>	BCRSV	DQ091194
	<i>Parietaria mottle virus</i>	PMoV	AY496069
	<i>Privet ringspot virus</i>	PrRSV	KT290040
	<i>Strawberry necrotic shock virus</i>	SNSV	AY743591
	<i>Tobacco streak virus</i>	TSV	U75538
Subgroup 2	<i>Asparagus virus 2</i>	AV-2	EU919667
	<i>Citrus leaf rugose virus</i>	CiLRV	U17726
	<i>Citrus variegation virus</i>	CVV	EF584665
	<i>Elm mottle virus</i>	EMoV	U34050
	<i>Lilac ring mottle virus</i>	LiRMoV	EU919669
	<i>Spinach latent virus</i>	SpLV	U93193
	<i>Tomato necrotic streak virus</i>	TomNSV	KT779205
Subgroup 3	<i>Tulare apple mosaic virus</i>	TAMV	AF226161
	<i>Apple mosaic virus</i>	ApMV	AF174585
	<i>Blueberry shock virus</i>	BIShV	KF031038
	<i>Lilac leaf chlorosis virus</i>	LLCV	FN669168
Subgroup 4	<i>Prunus necrotic ringspot virus</i>	PNRSV	AF278535
	<i>Fragaria chiloensis latent virus</i>	FCiLV	AY707771
Unassigned	<i>Prune dwarf virus</i>	PDV	AF277662
	<i>American plum line pattern virus</i>	APLPV	AF235165
	<i>Humulus japonicus latent virus</i>	HJLV	AY500237

Classification

The *Iilarvirus* genus was first recognized during the third meeting of the International Committee on the Taxonomy of Viruses in 1975. The genus, along with five other genera including *Alfamovirus*, *Anulavirus*, *Bromovirus*, *Cucumovirus* and *Oleavirus*, belongs to the *Bromoviridae* family. Among the six genera, *Iilarvirus* is particularly closely related to *Alfamovirus*. The name “*Iilarvirus*” is in fact a siglum derived from isometric labile ringspot viruses, describing several characteristics of ilarviruses: the shape of virions, the fragility or labile nature of viral particles and lastly, the frequently observed ring spotting symptom on infected hosts. Currently, the genus consists of 22 recognized members (Table 1). Previously ilarviruses were sub-grouped mainly based on serological properties with antibodies against the coat protein (CP). Accumulated sequence data support the serological relationships for most ilarviruses. However, extensive phylogenetic analyses also identify some species that had been inappropriately classified possibly due to conserved amino acid (aa) sequences and secondary structures in their CPs. Currently, the 22 recognized ilarviruses have been phylogenetically classified into four sub-groups in addition two unassigned viruses (Table 1, Fig. 1).

Virion Structure

Virions of ilarviruses are most commonly found as quasi-isometric shapes (Fig. 2(B)). The capsid of the virus is comprised of 180 coat protein (CP) units arranged in a $T = 3$ symmetry, ranging in diameter from 26 to 35 nm. Additionally, some members, such as Prune dwarf virus (PDV) and Prunus necrotic ringspot virus (PNRSV) also produce bacilliform particles with a diameter of 18–26 nm and 30–85 nm in length. As the virion contains the encapsulated genomic RNA, the size of virions is often related to the length and amount of RNA contained. The regions of the CP in some members is implicated in the formation and degree of lability of the virion.

Genome

Members of the *Iilarvirus* genus have a tripartite genome consisting of three separate positive-sense single-stranded RNA molecules, i.e., RNA1, RNA2 and RNA3, all of which bear a 5′-7-methyl-G cap structure but lack a poly A tail. The 3′ ends of genomic RNAs code for hairpin loop structures potentially forming intricate pseudoknots. The genomic organization of Tobacco streak virus (TSV), the type member of the *Iilarvirus* genus is presented in Fig. 2(A). Among three ilarviral genomic RNAs, RNA1 is the largest

Fig. 1 Phylogram showing nucleotide sequence relationships of ilarvirus RNA dependent RNA polymerase (ORF2a) with Barley stripe mosaic virus (BSMV) included as an outgroup (Accession NC_003478). Subgrouping (shown at right) is based on phylogenetic data, host range and serology. *Species unassigned to subgroups. Numbers at branch nodes shows percentage of bootstrap replicates in which that branch occurs. Abbreviations and sequence accession numbers are listed in [Table 1](#).

Fig. 2 (A) The genome structure of Tobacco streak virus, the type member of the *Iilarvirus* genus. Each single stranded positive sense RNA genomic fragment is shown and encoded proteins are shown as boxes with approximate nt and aa lengths, respectively. The complete genome of TSV isolate WC has a total length of 8622 nt. The P1 protein of TSV has 1094 aa with a molecular mass of 123.4 kDa. Encoded from ORF2a, the P2 protein has a sequence length of 800 aa and a mass of 91.5 kDa. The 2b protein has a sequence length of 205 aa, and a mass of 22.4 kDa. The movement protein (MP) of TSV has a length of 289 aa and a mass of 31.6 kDa. The coat protein (CP) encoded by ORF3b located in sgRNA4 is 237 aa in length and has a mass of 26.2 kDa. Each RNA fragment has a 5' cap shown as C and 3' tRNA-like structure shown as *. The large arrow denotes the transcription of sub-genomic RNA4. (B) A transmission electron micrograph showing virions of Prunus necrotic ringspot virus (PNRSV). Photograph courtesy of the Rothamsted Experimental Station, UK. The bar represents 100 nm.

genomic component, and contains a single open reading frame (ORF1), which encodes the P1 protein. This protein contains both methyltransferase (near the N-terminus) and helicase (near the C-terminus) domains. P1 may also contain a transmembrane domain at the C-terminus. It has been suggested that it is the P1 protein that recruits and anchors the viral RNA to the assembly site to support virus replication. Consistent with this assumption, subcellular localization studies suggest that P1 is associated with membranes of the vacuole, the endoplasmic reticulum (ER) and chloroplasts. Therefore, P1 is considered as an essential component of the viral replication complex (VRC). In subgroups 1 and 2, RNA2 is bicistronic with ORF2a and ORF2b. ORF2a encodes the P2 protein, which is the putative RNA dependent RNA polymerase (RdRp), whereas ORF2b codes for the 2b protein. P2 contains several conserved domains of RdRp such as the RNA binding domain and the GDD motif. Therefore, P2 is believed to be part of the VRC and directly responsible for biosynthesis of viral RNA. The 2b protein was originally proposed to be involved in systemic infection and was later proven to be a suppressor of post-transcriptional gene silencing to counteract against RNA silencing, a primary host antiviral defense mechanism. Members of subgroups 3 and 4 do not possess ORF2b. The third fragment, RNA3 is bicistronic and contains two ORFs, ORF3a and ORF3b. The former encodes a movement protein (MP), and the latter is expressed via a sub-genomic fourth RNA fragment (sgRNA4) for the translation of the CP. The ilarviral MP is a member of the 30K MP superfamily. Members of this superfamily are known to locate to the plasmodesmata (PD) and alter size exclusion limits of these cellular channels to assist virus cell-to-cell movement. The CP is a multifunctional protein and plays essential roles in different stages of the virus infection cycle such as virion formation and replication. A zinc finger motif has been identified in CPs of many plant viruses including some ilarviruses such as TSV and is presumed to be associated with nucleotide binding and virion formation. However, the fact that some ilarviruses such as PDV lack this motif supports the notion that this motif is not an absolute requirement for virion formation.

Infection Cycle

The infection cycle of ilarviruses may be artificially divided into several stages. As plant viruses usually have a small genome with limited coding capacity, they must hijack host pathways and factors to support their infection. Upon entry into host cells, ilarviruses undergo uncoating to remove the CP shell to expose the viral genome to the host translation machinery for translation on the rough ER. Subsequently, the P1 protein may target the membranes of preferred organelles such as the ER, vacuole and/or tonoplast and induces the formation of spherules or small vesicular structures where VRCs are assembled. The VRC catalyzes biosynthesis of the minus (−) strand RNA using the viral genomic RNA as template and further multiplies the (+) strand RNA using the newly synthesized (−) RNA as template. The (+) and (−) RNA strands are biosynthesized in an asymmetrical manner. During AMV replication, the ratio of (+) RNA versus (−) RNA is approximately 100:1. The progeny (+) RNAs are encapsidated by CPs to form virions. The newly synthesized RNA or virions may interact with MP, and the ribonucleoprotein complexes are transported intracellularly to the PD where they move from the primarily infected cells to neighboring cells. MP is definitely required for this process. For some ilarviruses, virion is not necessary for virus cell-to-cell spread, but the presence of CP is required for all ilarviruses to move intracellularly. For long-distance movement from the local infection to remote sites of the plant, the virus is transported from the mesophyll via bundle sheath cells, phloem parenchyma, and companion cells into phloem sieve elements and then following the source-to-sink flow of photo-assimilates and unloaded to sink tissues. Iilarviruses are likely transported for the long distance in the form of virions.

Replication

Most members in the *Bromoviridae* family possess transfer RNA-like structures (TLS) in the 3′ untranslated region (UTR) of their genomic RNAs, and these TLS regions interact with the cap at the 5′ end to circularize the viral RNA and promote the translation process. Different from these viruses, alfalfa mosaic virus (AMV) and ilarviruses lack TLS in their genomes. In this case, the CP is required to establish infection possibly by activation of viral protein translation and regulating transcription of new (+)/(−) viral RNA, a phenomenon termed genome activation. In lieu of TLS, this requirement of CP for virus replication is now a distinguishing feature of both *Alfavirus* and *Iilarvirus* genera. Viral replication mechanism has been studied more in depth for alfamoviruses than ilarviruses and due to the common feature of the CP requirement for genome activation has led to analogous conclusions for replication strategies. The process of genome activation is based on interactions between the viral CP and secondary structures found within the 3′ UTR of viral RNAs. A highly conserved RNA binding domain (RBD) containing crucial arginine (R) residue(s) is present in the N-terminal CP sequences of AMV and some ilarviruses, and the RNA-binding consensus motif in this RBD has the aa sequence Q/K/R-P/N-T-X-R-S-R/Q-Q/N/S-W/F/Y-A. Additional sequence analyses have identified a second putative RNA binding consensus sequence V(T/S)(R/N)RQ(S/R)RNA(A/R)RAAX(Y/F)R which is also conserved in at least six other ilarviruses. Some ilarviruses such as PNRSV do not have any of the two consensus RNA-binding sequences. However, the CP sequence in these viruses is R-rich. In the CP of PNRSV, there is a stretch of about 20 aa with five R residues that has the capacity to bind to the 3′ UTR of RNA3. In addition, the N-terminal region of the CPs of many ilarviruses including PNRSV possess a zinc finger motif that is believed to increase RNA binding affinity.

The process of genome activation is not species-specific, and some ilarviruses are able to use CPs from other ilarviruses to activate their genomes. This ability to reciprocally activate infectivity of the different viruses by their CPs can extend to the intergenus level. It

has also been shown that CP of AMV (an alfamovirus) and that of some ilarviruses can be interchanged to induce genome activation. In the absence of a translated CP, the presence of sgRNA4 is sufficient to result in an active genome as the CP is translated from this sub-genomic RNA. In the absence of sgRNA4 or CP, the transcription of viral RNA is preferred, however the addition of either one of these two elements leads to a shift towards translation. It is suspected that the binding of CP inhibits transcription, and that the RNA secondary structures enable binding by the CP. Complex secondary structures have been identified among sequenced ilarviruses, as the 3' UTRs of genomic RNAs possess conserved single stranded motifs of (A/U)(U/A/G)GC, which flank the regions potentially forming hairpin loop structures acting as binding sites for the CP. It has been suggested that the CP-RNA complex formed in ilarviruses are functionally analogous to the complex formed by poly A tract and the poly A binding protein in eukaryotes which is known to enhance translation of proteins. This has been further supported by the finding that the AMV CP does in fact bind to eukaryotic translation initiator complexes eIF4F and eIFiso4F.

Two models have been proposed to explain the role of the CP in the early stages of the ilarviral infection cycle. The conformational switching model proposes that the 3' UTR of AMV and ilarviruses can fold into two separate structures. The first is a pseudoknot which is functionally equivalent to the TLS and promotes the binding of viral RdRp and synthesis of negative strand RNA. The second structure is a linearized series of hairpin loops. This model proposes that early binding of CP causes a conformational change, or switch, unwinding the pseudoknot into a series of hairpin loops which cannot be bound by the RdRp. This model is supported by several lines of evidence from studies on AMV. The pseudoknot in the 3' UTR is essential for AMV replication and disruption of this structure inhibits viral replication. CP binding to the 3' UTR is inhibited when magnesium is added to stabilize the pseudoknot structures. The CP can bind to mutated 3' UTR sequences which are unable to form pseudoknots even after addition of magnesium. Consistent evidence has also been obtained from studies with ilarviruses. For example, the CP of PNRSV is unable to bind to the 3' UTR of genomic RNAs in the presence of magnesium. Overall, this model explains the role of CP in the regulation of RNA synthesis and protein translation.

The second model suggests that CP binding to the 3' UTR forms a complex critical for viral replication. This model contradicts the first model by predicting that the structure of the 3' UTR undergoes a different conformational change and CP binding to the 3' UTR creates a more compact structure. Structural analyses show that the unbound 3' UTR of AMV is flexible, supporting this model. When a short peptide identical in sequence to the AMV CP RNA binding domain is bound, the resulting CP-RNA complex is more rigid and compact due to base pairing between the AUGC repeats that flank hairpin loops. Modeling of the CP binding along the entire length of the AMV 3' UTR, shows that the predicted molecule has a compact, rod shaped structure with hairpins protruding from the center. In vitro studies have also shown that in absence of CP, the binding of the RdRp protein to labeled RNA is weak, and addition of CP significantly enhances the binding ability of RdRp to the labeled RNA. Therefore, CP binding to the 3' UTR promotes RNA transcription.

Transmission

Iilarviruses have several modes of transmission. The majority of ilarviruses have a relatively limited natural host range, with TSV as an exception which can infect a number of plant species naturally. All ilarviruses can infect a broad range of experimental herbaceous hosts via mechanical transmission. Iilarviruses naturally infecting herbaceous plants are easily transmitted mechanically via accidental damage during farming practices or by insects. Many ilarviruses naturally infect woody hosts such as stone fruit trees. However, the probability of mechanical transmission in the woody hosts is low. Perhaps the most common mode of ilarvirus transmission in these hosts is by vegetative propagation, which is a common horticultural practice. For example, grafting of scions to rootstocks is used for clonal propagation of woody fruit trees. In some cases, it is also used for herbaceous crop production (i.e., tomato, cucumber and watermelon) to take advantage of desirable traits of rootstocks such as disease resistance. In grafting, the use of infected material as either a root stock or scion facilitates the spread of viruses. Another method of vegetative propagation involves the direct planting of cuttings (i.e., alfalfa and hops), or division of crowns (i.e., rhubarb and asparagus). The propagation of new explants from an infected mother plant provides another simple yet common vector for virus spread. The finding that some ilarviruses are spread via seed poses a further challenge as rootstocks are commonly grown from seedlings. The spread of viruses by seed presents a challenge in the production of seed grown crops, and planting of uncertified seed stock has the potential to spread members of this genus at the beginning of a new growing season and even to new agricultural production regions.

Aside from transmission by vegetative propagation and seeds, ilarviruses may also transmit via plant-to-plant, i.e., hops, pollen grains and insects. For example, pollinating honeybees have been shown to transmit both PNRSV and PDV. The spread of TSV by thrips is well documented, and several species of thrips have been identified as vectors of ilarviruses. Feeding by thrips that carry virus-contaminated pollen, or feed on leaves covered by virus-contaminated pollen causes mechanical damage to the host plant, providing a point of entry for the virus.

Control

Treatment of any infections by plant viruses including ilarviruses is difficult. Therefore, methods to prevent viral infection should be implemented. Cross protection, also known as superinfection exclusion, describes the process in which the exposure to a mild

virus isolate induces the resistance against a more virulent, closely related isolate. The virus isolate selected for inoculation should be endemic to the growing region, ideally latent and showing minimal impact on the host. Cross protection does not offer broad resistance to unrelated viruses, and in fact, for some viruses, cross protection is only strain specific. A very successful example for the control of plant viruses using cross protection is to protect citrus from the devastating diseases caused by virulent isolate of *Citrus tristeza virus*, which belongs to the genus *Closterovirus* in the family *Closteroviridae*. Cross protection has also been reported to control infections by ilarviruses. Cherry rugose mosaic disease is a serious disease of sweet cherry and the causal agent is a virulent strain of PNRSV. Less virulent isolates of PNRSV have been identified for the control of the disease in sweet cherry. One possible mechanism of cross protection is RNA silencing. It has been suggested that virus infection is involved in the formation of double-stranded RNAs which trigger virus induced gene or RNA silencing (VIGS). VIGS explains why infection by an attenuated version of a virus can induce resistance to the virus isolates sharing similar sequences with the attenuated isolate. VIGS can also be used to silence host genes by insertion of a short fragment of a target gene into the attenuated virus. Recently, using a modified PNRSV, we have successfully silenced a gene in plum that is required for plum pox virus infection. The resulting plum plants show resistance to Plum pox virus.

Crop management to minimize risk of infection, and methods of early detection are the effective strategy to combat infections by ilarviruses and other plant viruses. Certification programs are important measures which should be implemented for introduction of viral pathogens. Many countries have programs to certify growing materials (seed, rootstocks, scion cuttings) as being free of viruses after testing. Using certified virus free materials is important when starting both perennial and annual crops. In particular for fruit trees which are propagated over decades in densely populated orchards such as members of the *Prunus* genus, the use of virus free material is a worthwhile long-term investment.

Hygiene practices including cleaning of pruning shears and other implements which contact plants should be routinely performed. When virus infections are found, common practices place an emphasis on sanitation and eradication including the removal and destruction of infected plants and plant material, removal of perennial weeds which may act as alternative hosts near annual growing fields. In response to the spread of viral diseases caused by transport of infected plant materials, some countries have imposed legislative methods to fight plant disease by enforcing strict regulations to restrict the movement of plant material. Control of vectors such as thrips or other insect vectors is another effective approach to minimize spread of insect- and/or pollen-transmitted viruses.

It is worth mentioning that the introduction of resistance using modern genetic engineering technologies has been demonstrated to be highly effective in the control of plant viruses. This type of resistance operates through RNA silencing by generation of transgenic plants that express a double-stranded RNA fragment sharing the sequence of the target virus. However, due to public concerns and regulatory barriers, this technology has not been widely used for the control of ilarviruses.

Symptoms and Pathogenesis

Symptoms induced by ilarviruses vary for different virus-plant combinations. As the name suggests, ringspot is a common symptom found on young leaves of ilarvirus-infected plants (**Fig. 3(A)**). Ringspots often become necrotic and the necrotic tissue dies leaving a shot-hole symptom pattern. Infection by TSV induces various symptoms in tobacco leaves including vein clearing, streaking, ringspots, stunting, leaf deformation and systemic necrosis. Cucumber plants infected with PDV initially show small chlorotic lesions, then a more severe mottling of leaves and stunted growth (**Fig. 3(B)**). Iilarvirus-infected plants often undergo an initial shock phase with the development of disease symptoms such as necrotic ringspots, followed by symptom attenuation and eventual recovery on new leaves. On woody plants, this disease process may take a few years. For example, infection of blueberry and cranberry by Blueberry shock virus, which is pollen-transmitted with the aid of honeybees, induces clear symptoms on the entire plant or some branches in the first 1–2 years. Leaves and flowers of infected plants appear blighted, and gradually drop off. After 1–3 years, the infected plants become asymptomatic. Cranberry bushes infected with TSV also show symptom recovery. However, different from the typical recovery phenomenon in which the abatement of symptoms is associated with antiviral RNA silencing and decreased viral accumulation (termed viral clearance), symptom recovery following infection by some ilarviruses may be caused by different mechanisms.

The molecular determinant for the recovery phenomenon in TSV has been identified. A single nucleotide substitution (A → G) in the intergenic region of RNA3, upstream of the transcription start site of sgRNA4 is responsible for the failure of a TSV isolate to initiate recovery in the host. Plants infected with this recovery deficient isolate develop disease symptoms which never subside. Interestingly, the viral titer in distal plant tissues is lower than that in the corresponding tissues of plants infected with the TSV wild type virus that can induce symptom recovery. These data support the assumption that symptom recovery in plants infected by at least some ilarviruses is not necessary to be related to viral titers. It is possible that ilarvirus-induced RNA silencing downregulates host resistance genes, which may contribute to an infection with abated symptoms where a higher viral titer is maintained.

Determinants of pathogenicity have been identified in some ilarviruses such as Asparagus virus 2 (AV-2) and PNRSV. The 2b protein encoded by AV-2 ORF2b acts as a suppressor of systemic RNA silencing to indirectly function as a determinant by counteracting the host plants defense mechanism. A more direct example of a disease determinant came from a study on PNRSV. In this study, full-length infectious cDNA clones derived from a pathogenically aggressive isolate (Pch12) and a mild isolate (Chr3) of PNRSV (**Fig. 3(C)**) were used to identify determinants of pathogenicity. By reassortment of genomic segments, swapping

Fig. 3 Ilarvirus-infected herbaceous experimental and natural host plants. (A) Healthy, asymptomatic leaf from sweet cherry (*Prunus avium* cv. Vogue) compared to leaf from an individual infected with PDV showing leaf deformation and yellowing. (B) Experimental herbaceous host cucumber (*Cucumis sativus* cv. Wisconsin) showing viral symptoms after being mechanically inoculated with homogenate prepared from PDV infected foliar tissue shown in A. Newly emerging and fully expanded symptomatic first true leaf and symptomatic second true leaf are magnified to show mottling and vein clearing symptoms at 5, 7, and 10 days post inoculation (DPI). (C) Symptoms induced by two infectious cDNA clones of PNRSV on its natural host cherry (*Prunus avium* cv. Bing) at 18 dpi. The two PNRSV isolates differ in symptom severity Chr3 induces the development of milder symptoms (necrotic spots on young leaves) whereas Pch12 causes severe top wilting and more severe necrosis. (D) Identification of pathogenicity determinants of PNRSV. Herbaceous host cucumber plants (*Cucumis sativus* cv. Straight Eight) were inoculated with two isolates of PNRSV via agrobacterium mediated infiltration of infectious cDNA clones. The mild isolate Chr3 shows minimal disease however the more aggressive isolate, Pch12 causes stronger disease symptoms in cucumber as well. The chimeric virus formed from the Chr3 isolate of PNRSV by the substitution of the 3' region of RNA1 from Pch12, and the substitution of asparagine to lysine at position 279 in RNA2 shows severe symptom development leading to the identification of pathogenicity determinants in PNRSV. Figs. 3(C and D) reproduced with permission from the American Phytopathological Society.

of partial genomic segments, and site-directed mutagenesis, it was shown that the 3' terminal nt sequence in RNA1 and aa K at residue 279 in RNA2-encoded P2 are the severe virulence determinants and are required for severe virulence and high levels of viral accumulation (Fig. 3(D)). PNRSV RNA1 and RNA2 seem to codetermine viral pathogenicity to adapt to alternating natural *Prunus* hosts, likely through mediating viral accumulation.

Diagnosis

Diagnosis of an infection by ilarviruses is temporally sensitive as initial shock symptoms subside, making the distinction of healthy and infected plants difficult. Symptoms are easily seen at the beginning of growing seasons before peak seasonal temperatures are reached; young, newly emergent leaves usually display the clearest symptoms. Common diagnosis techniques for other plant viruses are applicable to ilarviruses. Since ilarviruses usually have a wide experimental host range, indexing on herbaceous and woody indicators is an option for detection. The main advantages of this method are the relatively low costs and minimal reagents required. It should be noted that chemical additives such as 2-mercaptoethanol, ethylenediaminetetraacetic acid, cysteine hydrochloride, sodium diethyl-dithiocarbamate and polyvinyl-pyrrolidone are routinely added to inoculum preparations. These additives protect the virion from degradation while infected host tissue is homogenized which results in the release of endogenous RNA degrading enzymes, oxidizing agents, and tannins, all compounds that are known to degrade virions or inactivate them. There are several disadvantages to indexing including the long duration of experiments, the labor intensive nature of these studies and the low specificity. Generation of antibodies specific to some ilarviruses CPs has led to the commercial availability of serological diagnostic kits based on enzyme-linked immunosorbent assay (ELISA), which is fast, accurate, highly sensitive and specific, compared to other diagnostic methods. Disadvantages of serological diagnostic kits are that they are often highly specific, and are not sensitive to detect low titer of viruses. Nucleic acid-based detection techniques such as reverse transcription polymerase chain reaction (RT-PCR) serve as more powerful diagnostic tools. Multiplex PCR can be used to detect multiple viruses simultaneously with greater sensitivity and specificity compared to serological techniques. Indeed, multiplex PCR has also been shown to allow the detection of several ilarviruses simultaneously. Another powerful molecular technique is next generation sequencing (NGS). This method requires the greatest amount of time for preparation and is the most expensive option. However, NGS is a broad detection tool and additionally provides the user with incredibly extensive sequence data. Such sequencing data from infected hosts have been used to identify causal agents of plant disease including novel viruses, and even to obtain full-length genome sequences of some viruses.

Nomenclature

aa	Amino acid(s)	PTGS	Post-transcriptional gene silencing
CP	Coat protein or capsid protein	RdRp	RNA-dependent RNA polymerase
IRES	Internal ribosomal entry site	RTD	Readthrough domain
kb	Kilobases; the size of a ssDNA or ssRNA molecule	RT-PCR	Reverse transcription polymerase chain reaction
kDa	Kilodaltons; the size of a protein	S _{20,w}	Corrected sedimentation coefficient; extrapolated to that in water at 20°C and infinitely diluted
nm	Nanometer(s)	sgRNA	Sub-genomic RNA
nt	Nucleotide(s)	ssRNA	Single-stranded ribonucleic acid
ORF	Open reading frame	Vpg	Genome-linked protein
Poly(A)	Polyadenylated		

Glossary

Hemocoel The primary body cavity of most arthropods that contains most of the major organs and through which the hemolymph circulates.

Hemolymph A circulatory fluid in the body cavities (hemocoels) and tissues of arthropods that is analogous to blood and/or lymph of vertebrates.

Pseudoknot A folded RNA that contains two or more stem-and-loop structures where the loop of one stem-and-loop structure interacts with the stem of a second stem-and-loop structure.

Introduction

Viruses of the family *Luteoviridae* (luteovirids) cause economically important diseases in many monocotyledonous and dicotyledonous crop plants, including cereal grasses, cucurbits, legumes, lettuce, potatoes, sugar beets, and woody perennials. Yield reductions as high as 30% have been reported in epidemic years, although in some cases crops can be totally destroyed. Diseases caused by the viruses were recorded decades and even centuries before they were associated with the causal viruses. In many cases, the stunted, deformed, and discolored plants that result from luteovirid infections were thought to be the result of abiotic factors, such as mineral imbalances or stressful environmental conditions, or other biotic agents. This, along with their inability to be transmitted mechanically, delayed the initial association of the symptoms with plant viruses. For example, curling of potato leaves was first described in Lancashire, UK, in the 1760s, but was not recognized as a specific disease of potato until 1905 and to be caused by an aphid-transmitted virus until the 1920s. The causal agent, Potato leaf roll virus (PLRV), was not purified until the 1960s. Similarly, widespread disease outbreaks in cereals, probably caused by Barley yellow dwarf virus (BYDV), were noted in the United States in 1907 and 1949. In 1951, a virus was proposed as the causal agent. Other diseases caused by luteovirids, like yellowing of Suakwa vegetable sponge, which is caused by Suakwa aphid-borne yellows virus (SABYV), were not described until recently.

Taxonomy and Classification

Members of the family *Luteoviridae* were first grouped because of their common biological properties. These properties included persistent transmission by aphid vectors and the induction of yellowing symptoms in many infected host plants. 'Luteo' comes from the Latin luteus, which translates as yellowish. All luteovirids have small (c. 25 nm diameter) icosahedral particles, composed of one major and one minor protein component and a single molecule of positive-sense single-stranded RNA of approximately 5600 nt in length.

The family *Luteoviridae* is divided into three genera – *Luteovirus*, *Polerovirus* (derived from potato leaf roll), and *Enamovirus* (derived from pea enation mosaic) – based on the arrangements, sizes, and phylogenetic relationships of the predicted aa sequences of the open reading frames (ORFs). In some plant virus families, a single gene can be used to infer taxonomic and

Fig. 1 Phylogenetic relationships of the predicted amino acid sequences of the (a) RNA-dependent RNA polymerase (ORF2) and (b) major capsid protein (ORF3). When predicted amino acid sequences from ORF2 are used to group virus species the genera form three distinct groups. Using predicted amino acid sequences from ORF3, species of the genera *Luteovirus* and *Polerovirus* are intermingled in the tree. The resulting consensus trees from 500 bootstrap replications are shown. The numbers above each node indicate the percentage of bootstrap replicates in which that node was recovered. For virus abbreviations and GenBank accession numbers, see [Table 1](#).

phylogenetic relationships. Within the family *Luteoviridae*, however, different taxonomic relationships can be predicted depending on whether sequences of the replicase (ORF2) or coat protein (CP; ORF3) genes are analyzed ([Fig. 1](#)). ORFs 1 and 2 of the luteoviruses are most closely related to the polymerase genes of viruses of the family *Tombusviridae*, while ORFs 1 and 2 of the poleroviruses and enamoviruses are related to those of the family *Solemoviridae*. These polymerase types are distantly related in evolutionary terms. Consequently, it has been suggested that the family *Luteoviridae* be abolished and the *Luteovirus* genus be moved to the family *Tombusviridae* and the *Enamovirus* and *Polerovirus* genera be moved to the family *Solemoviridae*.

It is hypothesized that luteovirid genomic RNAs arose by recombination between ancestral genomes containing the CP genes characteristic of the family *Luteoviridae* and genomes containing either of the two polymerase types. For taxonomic purposes, the polymerase type has been the primary determinant in assigning a virus to a genus. For this reason, viruses for which only CP sequences have been determined have not been assigned to a genus. The current members of the family are listed in [Table 1](#). The genus *Luteovirus* contains nine species, and the *Polerovirus* genus has 19 species. The genus *Enamovirus* contains four species. In addition, with recent advances in virus detection by next-generation sequencing, over 60 partial or complete genome sequences have been deposited in GeneBank that potentially represent new virus species in the family.

Virion Properties

The sedimentation coefficients $S_{20,w}$ (in Svedberg units) for luteoviruses and poleroviruses range from 106 S to 127 S. Buoyant densities in CsCl are approximately 1.40 g cm^{-3} . The particles formed as result of the mixed infections by PEMV-1

and PEMV-2 sediment as two components. The $S_{20,w}$ are 107–122 S for B components (PEMV-1) and 91–106 S for T components (PEMV-2, an umbravirus). Virions are moderately stable and are insensitive to treatment with chloroform or nonionic detergents but are disrupted by prolonged treatment with high concentrations of salts. Luteovirus and polerovirus particles are insensitive to freezing.

Virion Structure and Composition

All members of the *Luteoviridae* have nonenveloped icosahedral particles with diameters of 25–28 nm (Fig. 2). Capsids are composed of major (21–23 kDa) and minor (54–76 kDa) CPs, which contain a C-terminal extension to the major CP called the readthrough domain (RTD). According to X-ray diffraction and molecular mass analysis, virions consist of 180 protein subunits, arranged in $T=3$ icosahedra. Virus particles do not contain lipids or carbohydrates. Using an X-ray crystallography-derived structure of virions of the Rice yellow mottle sobemovirus, which shares a CP aa sequence similarity of 33% with PLRV, it was possible to predict the virion structure of PLRV and other luteovirids.

Virions contain a single molecule of single-stranded positive-sense RNA of 5300–5900 nt. The RNAs do not have a 3' terminal poly(A) tract. A small protein (VPg) is covalently linked to the 5' end of polerovirus and enamovirus genomic RNAs. Cereal yellow dwarf virus - RPV (CYDV-RPV) also encapsidates a 322 nt satellite RNA that accumulates to high levels in the presence of the

Fig. 2 Transmission electron micrograph of Soybean dwarf virus particles magnified $240,000\times$. Virions (stained with uranyl acetate) are c. 25 nm in diameter, hexagonal in appearance, and have no envelope.

helper virus. Complete genome sequences have been determined for more than 30 species of the family *Luteoviridae* (Table 1). For several viruses, genome sequences have been determined from multiple isolates.

Genome Organization and Expression

Genomic RNAs of luteovirids contain five to seven conserved ORFs (Fig. 3). ORFs 1, 2, 3, and 5 are shared among all members of the *Luteoviridae*. Luteoviruses lack ORF0. Enamoviruses lack ORF4. Luteo- and polerovirus genomes contain a small ORF (ORF3a) upstream of ORF3. Luteovirus genomes contain a small ORF (ORF6) downstream of ORF5. The PLRV genome contains ORFs 6 and 7, within ORF5 and ORF8 within ORF1. In the enamo- and poleroviruses ORF0 overlaps ORF1 by more than 600 nt, which also overlaps ORF2 by more than 600 nt. In the luteoviruses, ORF1 overlaps ORF2 by less than 50 nt. In most luteo- and polerovirus genome sequences, ORF4 is contained completely within ORF3. A single, in-frame amber (UAG) termination codon separates ORF5 from ORF3.

Luteovirids have relatively short 5' and intergenic non-coding sequences. The first ORF is preceded by 21 nt in CABYV RNA and 142 nt in Soybean dwarf virus (SbDV) RNA. ORFs 2 and 3 are separated by 112–200 nt of non-coding RNA. There is considerable variation in the length of sequence downstream of ORF5, which ranges from 167 nt for CYDV-RPV to 650 nt for SbDV.

Luteovirids employ a wide range of strategies to express their compact genomes. ORFs 0, 1, 2, and 8 are expressed directly from genomic RNAs. Downstream ORFs are expressed from sub-genomic RNAs (sgRNAs) that are transcribed from internal initiation sites by virus-encoded RNA-dependent RNA polymerases (RdRps) from negative-strand RNAs and are 3' co-terminal with the genomic RNA. Since the initiation codon for ORF0 of polero- and enamoviruses is upstream of that of ORF1, translation of ORF1 is initiated by 'leaky scanning' in which ribosomes bypass the AUG of ORF0 and continue to scan the genomic RNA until they reach the ORF1 AUG. The protein products of ORF2 are expressed as a translational fusion with the product of ORF1. At a low but significant frequency during the expression of ORF1, translation continues into ORF2 through a –1 frameshift that produces a large protein containing sequences encoded by both ORFs 1 and 2 in a single polypeptide. The frameshift is mediated by a "slippery hepta-nucleotide sequence" (in the form X XXY YYZ) and a downstream RNA secondary structure termed a pseudoknot that causes ribosomes to pause and then shift back one nt before continuing translation in the new reading frame. ORF8, which has only been identified in PLRV, resides entirely within ORF1 in a different reading frame and encodes a 5 kDa replication-associated protein. To express ORF8, sequences within the ORF fold into a structure called an internal ribosome entry site (IRES), which recruits ribosomes to initiate translation about 1600 nt downstream of the 5' terminus of PLRV RNA.

ORFs 3a, 3, 4, and 5 are expressed through a leaky scanning mechanism from the 5' terminus of sgRNA1, which is located about 200 nt upstream of ORF3 at the end of ORF2 and extends to the 3' terminus of the genome. Translation of ORF3a is initiated at a non-AUG codon. ORF4 of most luteo- and poleroviruses is contained within ORF3. In all luteovirids, ORF5 is expressed only as a translational fusion with the products of ORF3 by readthrough of the UAG stop codon at the end of ORF3, which produces a protein with the product of ORF3 at its N-terminus and the product of ORF5 at its C-terminus. Readthrough is regulated by local and long-distance RNA-RNA interactions and in the case of luteoviruses and some poleroviruses requires the presence of CCXXX repeats (where X is any base) downstream of the ORF3 stop codon. Luteo- and poleroviruses produce second smaller sgRNA capable of expressing ORFs 6 and 7. Third sgRNAs, which do not appear to encode proteins, are produced at very high levels in luteoviruses, but at only low levels in PLRV.

Luteovirus (e.g. BYDV-PAV, 5677 nt)**Polerovirus (e.g. PLRV, 5882 nt)****Enamovirus (e.g. PEMV-1, 5705 nt)**

Fig. 3 Maps of the virus genomes of genera in the family *Luteoviridae*. Individual ORFs are shown with open boxes. The ORFs are staggered vertically to show the different reading frames occupied by each ORF. The yellow boxes indicate protein products with the predicted sizes listed to the right of each. The polyproteins encoded by ORF1 of enamo- and poleroviruses contain the protease and the genome-linked protein (VPg). The predicted amino acid sequences of proteins encoded by ORF2 are similar to RNA-dependent RNA polymerases. ORF3, which encodes the major coat protein, is separated from ORF5 by an amber termination codon. ORF4, when present, is most often contained within ORF3 and encodes a protein required for virus cell-to-cell movement. Luteo- and poleroviruses contain an ORF3a for which translation is initiated at a non-AUG codon. The 3' non-coding regions of luteoviruses contain translation enhancer elements (BTE). In PLRV, ORF7 is in-frame with the C-terminus of ORF5, and translation of ORF8 is mediated by an internal initiation ribosome entry site (IRES). Luteo- and poleroviruses produce three sub-genomic RNAs (sgRNAs), but enamoviruses produce a single sgRNA.

While enomo- and polerovirus RNAs contain 5' VPgs that interact with translation initiation factors, luteovirus RNAs contain only a 5' phosphate. Unmodified 5' termini are recognized poorly for translation initiation. To circumvent this problem, the BYDV-PAV genome contains a short sequence (BYDV translation element; BTE) located in the 3' non-coding region downstream of ORF5 that interacts with sequences near the 5' termini of genomic RNA and sgRNA1 to promote cap-independent translation initiation.

Post-transcriptional gene silencing (PTGS) is an innate and highly adaptive antiviral defense found in all eukaryotes that is activated by double-stranded RNAs (dsRNAs), which are produced during virus replication. Research into the functions of the proteins encoded by luteovirids has shown that the 28–34 kDa proteins encoded by ORF0 are strong suppressors of local and systemic PTGS for polero- and enamoviruses. Luteovirus genomes lack ORF0, but the product of ORF4 in luteoviruses functions to suppress systemic PTGS.

The ORF1-encoded proteins of enomo- and poleroviruses contain the VPg and a chymotrypsin-like serine protease that is responsible for the proteolytic processing of ORF1-encoded polyproteins. The protease cleaves the ORF1 protein internally to liberate the VPg, which is covalently attached to genomic RNA. The protein expressed by ORF8 of PLRV is required for virus replication. Luteovirid ORF2s have a coding capacity of 59–67 kDa for proteins that are very similar to known RdRps and hence likely represent the catalytic portion of the viral replicase.

For luteo- and poleroviruses ORF3a produces highly conserved 4.8–5.3 kDa proteins that are essential for long-distance movement. ORF3 encodes the major CP of the luteovirids, which ranges in size from 21 to 23 kDa. ORF5 has a coding capacity of 29–56 kDa. However, ORF5 is expressed only as a translational fusion with the product of ORF3 when, about 10% of the time, translation does not stop at the end of ORF3 and continues through to the end of ORF5. The ORF5 portion of this readthrough protein has been implicated in aphid transmission and virus stability. Experiments with PLRV and BYDV-PAV have shown that the N-terminal region of the ORF5 readthrough protein determines the ability of virus particles to bind to proteins produced by endosymbiotic bacteria of aphid vectors. Interactions of virus particles with these proteins seem to be essential for persistence of the viruses in aphids. Nucleotide sequence changes within ORF5 of PEMV-1 abolish aphid transmissibility. The N-terminal portions of ORF5 proteins are highly conserved among luteovirids while the C-termini are much more variable.

The luteo- and polerovirus genomes possess an ORF4 that is contained within ORF3 and encodes proteins of 17–21 kDa. Viruses that contain mutations in ORF4 are able to replicate in isolated plant protoplasts, but are deficient or delayed in systemic movement in whole plants. Hence, the product of ORF4 seems to be required for movement of the virus within infected plants. This hypothesis is supported by the observation that enamoviruses lack ORF4. While luteo- and poleroviruses are limited to phloem and associated tissues, the enamovirus PEMV-1 is able to move systemically through other plant tissues in the presence of PEMV-2, which under natural conditions invariably coexists with PEMV-1.

Some luteo- and polerovirus genomes contain small ORFs within and/or downstream of ORF5. In luteoviruses, no protein products have been detected from these ORFs in infected cells. BYDV-PAV genomes that do not express ORF6 are still able to replicate in protoplasts. The predicted sizes of the proteins expressed by ORFs 6 and 7 of PLRV are 7.1 and 14 kDa, respectively. Based on mutational studies, it has been proposed that these genome regions may regulate transcription late in infection.

Evolutionary Relationships

As mentioned above, viruses in the family *Luteoviridae* have replication-related proteins that are similar to those in other plant virus families and genera. The luteovirus replication proteins encoded by ORFs 1 and 2 resemble those of members of the family *Tombusviridae*. In contrast, the serine protease-VPg-polymerase complex of polero- and enamoviruses resemble those of viruses in the family *Solemoviridae*. The structural proteins of some members of the *Sobemovirus* genus in the family *Solemoviridae* also are similar to the major CP of luteovirids.

Host Range and Transmission

Several luteovirids have natural host ranges largely restricted to one plant family. For example, BYDV and CYDV infect many grasses, BLRV infects mainly legumes, and CtRLV infects mainly plants in the family Apiaceae. Other luteovirids infect plants in several or many different families. For example, Beet western yellows virus (BWYV) infects more than 150 species of plants in more than 20 families. As techniques for infecting plants with recombinant viruses have improved, the experimental host ranges of luteovirids have been expanded to include plants on which aphid vectors would not normally feed. For example, BYDV, CYDV, PLRV, and SbDV have been shown to infect *Nicotiana* species when inoculated biolistically with viral RNA or using *Agrobacterium tumefaciens* harboring binary plasmids containing infectious copies of the virus genomes even though those species had not been described previously as experimental hosts for the viruses. These results suggest that feeding preferences of vector aphids play important roles in defining luteovirid host ranges.

Luteovirids are transmitted in a circulative manner with varying efficiencies by at least 25 aphid species. With the exception of the enamovirus PEMV-1, members of the family *Luteoviridae* are transmitted from infected plants to healthy plants in nature only by the feeding activities of specific species of aphids. There is no evidence for replication of the viruses within aphid vectors. *Myzus*

Fig. 4 Circulative transmission of viruses of the family *Luteoviridae* by vector aphids. While feeding from sieve tubes of an infected plant, an aphid (shown in cross section) acquires virus particles, which travel up the stylet, through the food canal, and into the foregut. The virions are actively transported across cells of the posterior midgut and/or hindgut into the hemocoel in a process that involves receptor-mediated endocytosis. Virions then passively migrate through the hemolymph to the accessory salivary gland where they are again transported by a receptor-mediated process to reach the lumen of the gland. Once in the salivary gland lumen, the virions are expelled with the saliva into the vascular tissue of host plants. Aphids can retain the ability to transmit virus for several weeks. Hindgut membranes usually are much less selective than those of the accessory salivary glands, which is why viruses that are not transmitted by a particular species of aphid often accumulate in the hemocoel, but do not traverse the membranes of the accessory salivary gland.

persicae is the most common aphid vector of luteovirids that infect dicots. Several different species of aphids transmit luteovirids that infect monocotyledonous plants (BYDV and CYDV) in a species-specific manner.

Circulative transmission of the viruses is initiated when aphids acquire viruses from sieve tubes of infected plants during feeding. The viruses travel up the stylet, through the food canal, and into the foregut (Fig. 4). The viruses then are actively transported across the cells of the alimentary tract into the hemocoel in a process that involves receptor-mediated endocytosis of the viruses and the formation of tubular vesicles that transport the viruses through epithelial cells and into the hemocoel. Luteovirids are acquired at different sites within the gut of vector aphids. PLRV and BWYV are acquired in the posterior midgut. BYDV, CYDV, and SbDV are acquired in the hindgut. CABYV is taken up at both sites. Viruses then passively migrate through the hemolymph to the accessory salivary gland where the viruses must pass through the membranes of the accessory salivary gland cells in a similar type of receptor-mediated transport process to reach the lumen of the gland. Once in the salivary gland lumen, viruses are expelled with saliva into vascular tissues of host plants. Since large amounts of virus can accumulate in the hemocoel of aphids, they may retain the ability to transmit virus for several weeks. Typically, hindgut membranes are much less selective than those of the accessory salivary glands. Consequently, viruses that are not transmitted by a particular species of aphid often are transported across gut membranes and accumulate in the hemocoel, but do not traverse the membranes of the accessory salivary gland.

The RTD of the minor capsid protein plays a major role in aphid transmission of luteovirids. The RTD interacts with symbionin produced by endosymbiotic aphid-borne bacteria, which may protect virions from degradation by the aphid immune system. The specificity of aphid transmission and gut tropism has been linked to the RTD in multiple luteovirids.

Unlike other luteovirids, PEMV-1 can be transmitted by rubbing sap taken from an infected plant onto a healthy plant, in addition to being transmitted by aphids. This difference in transmissibility is dependent on its multiplication in cells co-infected with PEMV-2, but aphid transmissibility can be lost after several mechanical passages.

Replication

Luteovirids infect and replicate in sieve elements and companion cells of the phloem and occasionally are found in phloem parenchyma cells. PEMV-1 can move systemically into other tissues in the presence of PEMV-2. Virus infections commonly result in cytopathological changes in cells that include formation of vesicles containing filaments and inclusions that contain viral RNA and virions. The subcellular location of viral RNA replication has not been determined unequivocally. However, early in infection, negative-strand RNAs of BYDV-PAV are first detected in the nucleus and later in the cytoplasm, which suggests that at least a

portion of luteovirus replication occurs in the nucleus. Synthesis of negative-strand RNA, which requires tetraloop structures at the 3' end of BYDV-PAV genomic RNAs, is detected in infected cells before the formation of virus particles. Late in infection, BYDV-PAV sgRNA2 inhibits translation from genomic RNA, which may promote a switch from translation to replication and packaging of genomic RNAs.

Virus–Host Relationships

While some infected plants display no obvious symptoms, most luteovirids induce characteristic symptoms that include stunting, leaves that become thickened, curled or brittle, and yellow, orange, or red leaf discoloration, particularly of older leaves of infected plants. These symptoms result from phloem necrosis that spreads from inoculated sieve elements and causes symptoms by inhibiting translocation, slowing plant growth, and inducing the loss of chlorophyll. Symptoms may persist, may vary seasonally, or may disappear soon after infection. Temperature and light intensity often affect symptom severity and development. In addition, symptoms can vary greatly with different virus isolates or strains and with different host cultivars.

Yield losses caused by luteovirids are difficult to estimate because the symptoms often are overlooked or attributed to other agents. US Department of Agriculture specialists estimated that yield losses from BWYV, BYDV, and PLRV infections were over \$65 million during the period 1951–60. Plants infected at early stages of development by luteovirids suffer the most significant yield losses, which often are linearly correlated with the incidence of virus infection.

Epidemiology

Luteovirid infections have been reported from temperate, subtropical, and tropical regions of the world. Some of the viruses are found worldwide, such as BWYV, BYDV, and PLRV. Others have more restricted distribution, such as tobacco necrotic dwarf virus, which has been reported only from Japan, and groundnut rosette assistor virus, which has been reported only in African countries south of the Sahara.

Luteovirids infect annual and perennial, cultivated and wild plants. In annual crops, the viruses must be reintroduced each year by their aphid vectors, sometimes from native perennial hosts. Some viruses are disseminated in infected planting material. For example, infected potato tubers are the principal source of inoculum for new epidemics of PLRV. Consequently, programs to produce clean stock are operated around the world to control these viruses. Alate, that is, winged, aphid vectors may transmit viruses from local cultivated, volunteer, or weed hosts. Alternatively, alate aphids may be transported into crops from distant locations by wind currents. These vectors may bring the virus with them, or they may first have to acquire virus from locally infected hosts. The agronomic impact of luteovirid diseases depends both on meteorological events that favor movement and reproduction of vector aphids and susceptibility of the crop at the time of aphid arrival. Only aphid species that feed on a particular crop plant can transmit virus. Aphids that merely probe briefly to determine a plant's suitability will not transmit the viruses. Secondary spread of the viruses is often primarily by apterous, that is, wingless, aphids. The relative importance of primary introduction of virus by alate aphids and of secondary spread of virus by apterous aphids in disease severity varies with the virus, aphid species, crop, and environmental conditions.

Some members of the family *Luteoviridae* occur in complexes with other members of the family or with other plant viruses. For example, BYDV and CYDV often are found co-infecting cereals; BWYV and SbDV are often found together in legumes; and PLRV is often found co-infecting potatoes with Potato virus Y and/or Potato virus X. Some other plant viruses depend on luteovirids for their aphid transmission, such as the Groundnut rosette virus, Carrot mottle virus, and Bean yellow vein banding virus (all umbraviruses), which depend on Groundnut rosette assistor virus, Carrot red leaf virus, and PEMV-1, respectively.

Diagnosis

An integral part of controlling luteovirid diseases is accurate diagnosis of infection. Because symptoms caused by luteovirids often resemble those induced by other biotic and abiotic factors, visual diagnosis is unreliable and other methods have been developed. Initially, infectivity, or biological, assays were used to diagnose infections. These techniques also have been used to identify species of vector aphids and vector preferences. In bioassays, aphids are allowed to feed on infected plants and then are transferred to indicator plants. These techniques are very sensitive but can require several weeks for symptoms to develop on indicator plants. The strong immunogenicity of luteovirids has facilitated development of very specific and highly sensitive serological tests that can discriminate different luteovirids and sometimes even strains of a single virus species. Poly- and monoclonal antibodies for virus detection are produced by immunizing rabbits and/or mice with virus particles purified from infected plants. Techniques also have been developed to detect viral RNAs from infected plant tissues by reverse transcription-polymerase chain reaction (RT-PCR), which can be more sensitive and discriminatory than serological diagnostic techniques. High-throughput sequencing of plant transcriptomes has become a powerful tool for identification of new luteovirids and characterization of virus complexes infecting plants. Even so, serological tests are the most commonly used techniques for the detection of infections because of their simplicity and speed.

Control

Because methods are not available to cure luteovirid infections after diagnosis, emphasis has been placed on reducing losses through the use of tolerant or resistant plant cultivars and/or on reducing the spread of viruses by controlling aphid populations. Many luteovirids are transmitted by migrating populations of aphids that occur at similar times each year. For those virus–aphid combinations, it is sometimes possible to plant crops so that young, highly susceptible plants are not in the field when the seasonal aphid migrations occur. Insecticides have been used in a prophylactic manner to reduce crop losses. While insecticide treatments do not prevent initial infections, they can greatly limit secondary spread of aphids and therefore of viruses. In some instances biological control agents such as predatory insects and parasites have reduced aphid populations significantly. Genes for resistance or tolerance to infection by luteovirids have been identified in most agronomically important plant species infected by the viruses. For BYDV, PLRV, and SbDV, transgenic plants that express portions of the virus genomes have been produced through DNA-mediated transformation. In some cases, the expression of these virus genes in transgenic plants confers higher levels of virus resistance than naturally occurring plant resistance genes.

Glossary

3'CITE An RNA tertiary structure located in the 3'UTR which binds to translation initiation factor(s) and to a structure nearer the 5' end of the RNA which allows assembly with a ribosome and initiation factors for translation.

Cryo-electron microscopy Technique for rapidly cooling dilute aqueous biomolecules to determine structures at the molecular level.

Movement proteins Viral proteins that assist in the movement of vRNA or virions through plasmodesmata, the tube-like structures connecting one plant cell to another.

Phloem Vascular tissue that transports small molecules throughout the plant.

Plasmodesmata Microscopic membrane channels through plant cell walls that allow small molecules to readily move between plant cells. Plasmodesmata are internally coated by the endoplasmic reticulum.

Poaceae A family of monocotyledonous plants commonly called the grass family.

Potyvirus A virus in the family *Potyviridae* which contains the genera *Potyvirus* and *Tritimovirus*.

Protoplast A plant cell (either from an undifferentiated plant cell culture or from a plant tissue such as a leaf) that has been treated in an isotonic solution with a mixture of enzymes that degrades the cell wall, leaving membrane-bound structures similar to single animal cells.

Satellite RNA Non-coding ssRNAs dependent on a helper virus for replication.

Satellite virus ssRNA encoding only a CP that requires a helper virus to replicate.

Silencing suppressor - (suppressor of silencing) Virally encoded proteins from diverse virus families that interfere with host production or effectiveness of siRNAs.

Small interfering RNAs (or silencing RNAs), 20–25 bp RNAs with 2 nt 3' overhanging ends that target invading viral RNAs or cellular RNAs for degradation in eukaryotic cells.

Synergism/synergistic disease When disease symptoms of a double infection are more severe than the sum of each single infection.

Tombusvirid Member of the family *Tombusviridae*.

Classification

Realm *Riboviria*, family *Tombusviridae*, subfamily *Procedovirinae*, genera *Machlomovirus*, and *Panicovirus*. The genus *Machlomovirus* contains only one species, *Maize chlorotic mottle virus*, while the genus *Panicovirus* contains three species: *Cocksfoot mild mosaic virus*, *Panicum mosaic virus* (the type species) and *Thin paspalum asymptomatic virus* (Table 1).

Virion Structure

Like the majority of plant viruses, Maize chlorotic mottle virus (MCMV) and *Panicum mosaic virus* (PMV) are composed of only the viral genome within a protein shell made of multiple copies of a single coat protein (CP). Similar smooth virion structures have been determined for MCMV (cryo-electron microscopy) and PMV (X-ray diffraction). Both viruses are ~30 nm in diameter, exhibit icosahedral symmetry, and are composed of 180 subunits of a single 25 or 26 kDa CP that encapsidates one copy of their single ssRNA genomes (Fig. 1).

Table 1 List of members of the genera *Machlomovirus* and *Panicovirus* in the family *Tombusviridae*. Type species are in bold

Subfamily/Genus	Species	Acronym	Accession #	Length (nt)	# sgRNAs ^a
Procedovirinae					
Machlomovirus	Maize chlorotic mottle virus	MCMV	NC003627	4437	1
Panicovirus	<i>Cocksfoot mild mosaic virus</i>	CMMV	NC011108	4198	1
	Panicum mosaic virus	PMV	NC002598	4326	1
	<i>Thin paspalum asymptomatic virus</i>	TPAV	NC021705	4195	1

Genomes

The genome organizations of the 16 genera in the family *Tombusviridae* fit one of four patterns. MCMV and panicoviruses have a carmovirus-like genome organization in which the cell-to-cell MP ORFs immediately follow the RdRp ORF, and the CP ORF is located at the 3' end of the genome. Like other members of the family *Tombusviridae*, the vRNA for both viruses is uncapped and does not contain a poly(A) tail. MCMV (4437 nt), PMV (4326 nt) and the other two recognized panicoviruses have larger genomes than other tombusvirids that form smooth virions (lacking a protruding domain [24.5–29.9 kDa CPs]), and are longer than some aureusviruses, which encode CPs with protruding domains (35.1–42.2 kDa). The size reflects the presence of larger genes for the pre-readthrough region (RAP) of their replicases, which encode carboxyl regions with high homology to other family members while the amino-terminal extensions are unique to each genus. MCMV encodes two overprinted genes that, 30 years after the first vRNA submission to GenBank, are still completely unique. And unlike all other tombusvirids, the RAP ORF start codon is preceded by the start codon of the unique 32 kDa ORF. P32 and p50, due to the p32 ORF overlap of the p50 ORF, are highly charged. P32 has a pI ~ 4 while p50 has a pI ~ 10 which causes an anomalous (opposite) migration pattern of the two proteins in SDS-PAGE. Initially, it was predicted that the second unique MCMV ORF encoding an extension of the upstream MP (p7a) was expressed via stop codon readthrough to make a 31 kDa protein. But the p7a ORF stop codon is not in a context that is likely to support readthrough, so it is more likely that the second unique gene is expressed from another non-canonical start codon to make a 23 kDa protein. PMV encodes an unrelated unique gene overprinted within its CP ORF that encodes a 15 kDa protein which is only found in viruses in the genus *Panicovirus* (Fig. 2).

Hosts and Distribution

MCMV was initially found in maize (*Zea mays*), also known as corn, in Peru in 1973. MCMV next spread long-distance via contaminated seeds to Kansas and Nebraska in midwestern USA (1976). Testing of native grasses and common cereal crops

Fig. 2 Genome organizations of MCMV and PMV. Thick black lines mark the gRNAs while the thinner short lines are sgRNAs. ORFs encoding proteins with the same function are the same color while unique ORFs have unique colors (identified below the genomes) along with symbols for readthrough stop codons and noncanonical start codons. ORFs are located relative to the RdRp reading frame (– 1 above and + 1 below).

indicated that MCMV-K and MCMV-P systemically infected 19 and 15 species, respectively, including wheat and barley. Since MCMV seed transmission rate varies widely for different maize cultivars, and maize production has increased worldwide, the virus has spread to most continents. Over the years MCMV has appeared in Mexico, additional South American countries, Hawaii, Thailand, Mainland China, and Taiwan, seven countries in Eastern Africa, and most recently was detected in maize and johnsongrass in Spain. MCMV has infected additional *Poaceae* crops in Africa (sorghum, sugarcane, and finger millet) and was found in johnsongrass, a common agricultural weed which grows nearly worldwide. China has reported MCMV in maize, sugarcane, sorghum, and Job's tears (*Coix lacryma-jobi*).

PMV infects switchgrass (*Panicum virgatum*) which grows in most of the USA and Canada except the farthest Western & Northern States/Provinces. PMV mostly occurs in 12 states: Nebraska-to-Texas, and Eastern States below parallel 36°30'N except Tennessee. PMV also infects the warm-season lawn grasses St. Augustine grass (*Stenotaphrum secundatum*) and centipedegrass (*Eremochloa ophiuroides*), and the model organism purple false brome (*Brachypodium distachyon*). For the two other recognized panicoviruses, CMMV infects a cool season perennial grass (*Dactylis glomerata*) native to northern Europe, temperate Asia, and northern Africa that is grown in hay meadows and pastures, while TPAV was found in a native tallgrass prairie in Oklahoma, USA. Bermuda grass latent virus (BGLV), found in South-Eastern USA, is likely another asymptomatic panicovirus that infects Bermuda grass (*Cynodon dactylon*) which is a warm-season grass used for sports fields and lawns.

Life Cycle

For both MCMV and PMV, upon entering a plant cell the virion disassembles, exposing the vRNA, which, based on work with many tombusvirids, folds into complex secondary and tertiary structures that regulate the various stages of virus replication and gene expression via LDRIs, including translation, replication, and sgRNA synthesis. Both viruses replicate in the cytoplasm, and the vRNA (and later the sgRNA) engages with ribosomes via unique genus-specific 3' CITEs: the PMV-like 3' CITE (PTE) and a PTE variant for MCMV in their 3' UTRs. Base-pairing between a small stem loop in the 5' UTRs of both vRNA and sgRNA with a sequence in the 3' CITE allows the circularization function for each RNA that is typically performed for eukaryotic mRNAs by translation factors that bind poly(A) tails and m⁷G-caps. RAP and lower quantities of RdRp are synthesized from vRNA, and RAP and RdRp are the only viral proteins required for replication in protoplasts for both viruses. Replication, including (–)strand synthesis, most likely occurs in membrane-bound vesicles on mitochondrial or peroxisomal membranes as has been shown for some tombusviruses. During a viral infection (–)RNA accumulates to levels that allow isolation of dsRNA from leaf tissue. For MCMV, p32 is also synthesized from vRNA at low levels from the 5' overprinted ORF. MCMV p32 is not required for replication in protoplasts or plants, but infectious transcripts lacking p32 expression accumulate virus at ~1/3 of the level of wild type in protoplasts, and produce delayed, mild infections in maize plants, suggesting this gene might encode a unique suppressor of silencing. A single large sgRNA is synthesized for MCMV and PMV, which contains all the ORFs necessary for cell-to-cell and long distance movement. For both species, proteins expressed from the two small ORFs (MP1 and MP2) are required for cell-to-cell movement, while MP1, MP2, and CP are required for efficient long-distance movement. The unique ORFs in PMV and MCMV overlapping their CP ORFs encode proteins required for long distance viral movement. Fortuitously, when MCMV gene functions were analyzed, the mutations introduced to “stop” the ability to read through the MCMV p7a stop codon also altered the noncanonical start codon for p23, so the function of the downstream ORF was accurately identified. MCMV infections also produce a small 337 nt 3' coterminal RNA, sgRNA2. This is likely an exoribonuclease-resistant RNA (xrRNA) produced by a cellular exoribonuclease, which enhances the viral infection. xrRNAs have been identified in viruses from five other tombusvirid genera.

Epidemiology

PMV and other panicoviruses are transmitted via mechanical inoculation, usually lawnmowers (St. Augustine grass and centipede grass) or other grass-harvesting/cutting tools such as hay swathers and balers for switchgrass. MCMV is also readily transmitted via mechanical inoculation, but it has also been shown to be transmitted via corn rootworm beetles and thrips. It is likely that transmission via these insects occurs through the maceration of the tissue (beetles) or rasping/sucking mouthparts of the thrips after the insects have fed on infected plants, which would be mechanical inoculation via insects. MCMV also exhibits transmission through the soil since immediately replanting maize in fields that contained MCMV-infected maize results in a high rate of infection of the new crop. Some chytrid fungi in the genus *Olpidium* can transmit tombusviruses via binding of assembled virions to fungal zoospores, so a fungus may be the vector for MCMV transmission via soil. Growing a nonhost crop such as soybeans between maize crops stops soil-transmission.

Pathogenesis

Both MCMV and PMV are part of highly destructive synergistic diseases that are produced by different co-infections. SAD is caused by coinfection of PMV and Satellite panicum mosaic virus (SPMV) or the closely related Satellite St. Augustine decline virus (SSADV) in St. Augustine grass. PMV supports the replication of SPMV (824 nt) and two subviral RNAs, satS (375 nt) and satC (444 nt). SPMV encodes its own CP (17 kDa), and SPMV forms icosahedral virions that exclusively encapsidate its own RNA or PMV satRNA. Encapsidated SPMV accumulates in the cytosol, and SPMV CP also accumulates in the cell wall, nuclear membranes, and nucleolus. The satRNA satS replicates in pearl millet protoplasts or plants when RNA from PMV or PMV + SPMV are present, and satS decreases PMV and SPMV accumulation, thereby decreasing disease symptoms.

While single infections of MCMV produce relatively mild symptoms in maize that vary with the cultivar, double infections with the maize-infecting potyviruses [(Maize dwarf mosaic virus (MDMV), Johnson grass mosaic virus (JGMV), Sugarcane mosaic virus (SCMV)], or the tritivirus Wheat streak mosaic virus (WSMV) causes a severe synergistic infection called CLN or MLN. Potyviruses are transmitted by aphids while WSMV is transmitted by the wheat curl mite. In most synergistic diseases involving potyvirids, the potyvirus accumulates to about the same level in single or double infections, while the other virus (MCMV in CLN) can increase dramatically, and this occurs for MLN caused by potyviruses. This is probably due to the highly effective potyvirus silencing suppressor, HC-Pro. In MCMV + WSMV infections of maize, the level of WSMV also increased in doubly-infected plants, and the increase was temperature-dependent. The recent MLN outbreak in Africa involved SCMV and JGMV, while SCMV is associated with CLN in China.

Diagnosis

Antibody-based detection kits are commercially available for both MCMV and PMV, and both viruses are readily detected from leaf tissue via RT-PCR using primers within the sgRNA region.

Prevention

Scrupulous cleaning of lawn equipment and farming equipment (balers, tillers, combines) decreases the chance of transmitting the viruses to additional fields. There are no treatments for living infected plants. Crop rotation of maize with any dicot crop stops soil transmission of MCMV.

This is an update of D.P. Martin, D.N. Shepherd, E.P. Rybick, Maize Streak Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00707-X](https://doi.org/10.1016/B978-012374410-4.00707-X).

Abbreviations

C-ori complementary strand (i.e., the half of the DNA duplex that is not packaged into virus particles) origin of replication.

CP coat protein. The only protein component of the virus particle also believed to be involved in nuclear trafficking and cell-to-cell movement of viral DNA.

LIR long or large intergenic region containing the origin of virion strand replication and gene promoters.

MP movement protein. A small (c. 10 kDa) protein believed to be involved in intercellular virus movement via plasmodesmata.

Rep replication-associated protein involved in the initiation of virion strand replication.

RepA a truncated version of Rep with a unique C-terminal domain believed to be involved in regulation of host and/or virus gene expression.

SIR short or small intergenic region containing gene polyadenylation signals and the origin of complementary strand replication.

V-ori virion strand (i.e., the half of the DNA duplex that is packaged into virus particles) origin of replication.

Glossary

Agro-infection Technique used for the infection of host plants with cloned virus genomes involving transfer of virus DNA into the nuclei of host cells by the bacterium *Agrobacterium tumefaciens*.

Agro-inoculation See agro-infection.

Bicistronic Contains two protein-coding regions within a single mRNA transcript.

Capsomer A subunit of the mature virus particle containing an ordered series of polymerized coat protein molecules.

Cicadulina spp. A group of leafhopper species involved in transmission of MSV.

Oviposition Egg-laying. To oviposit means to lay eggs.

Plastochron The time interval between successive leaf primordia, or the attainment of a certain stage of leaf development.

Viruliferous A state in which an MSV vector species is carrying and is capable of transmitting the virus.

Introduction

Maize streak virus (MSV) is the causal agent of maize streak disease (MSD), one of the most serious viral diseases of maize in Africa. It is a major contributor to the continent's food security problems and is endemic throughout Africa south of the Sahara. It is also found on the Indian Ocean islands of Madagascar, Mauritius, and La Réunion. There is no obvious barrier to spread of the virus outside of this region; hence it should be considered as a serious potential problem for other as yet unaffected maize-growing areas.

History and Taxonomy

"The disorder of the mealie plant, locally described as "Mealie Blight", "Mealie Yellows", or "Striped Leaf Disease", belongs to a group of plant troubles arising from obscure causes ..." was how MSD was first described by Claude Fuller in 1901 in Natal, South Africa. Fuller mistakenly attributed the disease to a soil disorder, but in retrospect it is quite clear that the "mealie (a local word for maize or corn) variegation" he described and drew in minute detail can be attributed to MSV.

The first milestone in MSD research was reached in 1924, when Storey determined that a virus transmitted by leafhopper species of the genus *Cicadulina* (Fig. 1) was the causal agent of MSD. Storey named the virus "maize streak virus", and was also the first to determine both the genetic basis of MSV transmission by *Cicadulina mbila*, and the heritability of MSD resistance in maize.

When MSV particles were first purified in 1974 they were found to have a novel twinned quasi-icosahedral (geminiate) shape (Fig. 2), from which the name "geminivirus" was derived. This was followed by the unexpected discovery in 1977 that geminivirus particles contain circular single-stranded DNA (ssDNA); a genome type never before observed in plant viruses. These novel characteristics led to the proposal of a new virus group – the geminiviruses – comprising MSV and other viruses with geminate particles and ssDNA genomes. *Maize streak virus* is now recognized as the type species of the genus *Mastrevirus*, in the family *Geminiviridae*.

Host Range and Symptoms

While most notorious for the yield losses it causes when infecting maize, MSV also infects over 80 other grass species including the economically important crops wheat, barley, and rye. In susceptible maize and grass genotypes, the virus first causes symptoms between 3 and 7 days after inoculation. These first appear as almost circular pale spots of 0.5–2 mm diameter in the lowest exposed portions of the youngest leaves. Later, fully emerged symptomatic leaves show veinal streaks from a few millimeters long to the entire length of the leaf and between 0.5 and 3 mm wide. These streaks often fuse laterally and symptomatic leaves may become >95% chlorotic (**Fig. 2**).

Plants are worst affected when infected within a few days of coleoptile emergence; symptoms only develop above the site of inoculation on newly emerging leaves. Susceptible varieties may display severe stunting as well as very severe streaking. Afflicted plants will frequently produce deformed cobs or may fail to produce cobs altogether and per-field yield losses can reach 100% when susceptible maize genotypes are infected early.

Of the eleven major MSV strains so far identified (designated MSV-A through MSV-K; (**Fig. 3**)), only MSV-A produces economically significant infections in maize. The “grass-adapted” MSV strains (MSV-B, -C, -D, -E, -F, -G, -H, -I, -J and -K) differ from MSV-A types by 5%–25% in nucleotide sequence, and produce substantially milder symptoms in maize than do MSV-A viruses. In many cases these grass-adapted strains are incapable of producing symptomatic infections in MSV-resistant maize genotypes.

Diversity and Evolution

MSV is closely related to the other distinct ‘African streak’ mastreviruses, Panicum streak virus, Sugarcane streak virus, Sugarcane streak Egypt virus, and Sugarcane streak Reunion virus, with which it shares ~65% genome sequence identity. It is, however, most similar to, although not necessarily more closely related to, an isolate of *Digitaria streak virus* from the Pacific island of Vanuatu, with which it shares ~67% genome sequence identity (**Fig. 3**).

Fig. 3 Phylogenetic relationships between the full genome sequences of different MSV strains. The tree is constructed using the maximum-likelihood method (HKY model transition and transversion weight determined from the data and 100 bootstrap replicates) and numbers associated with branches indicate degrees of bootstrap support for those branches. Branches with less than 70% support have been collapsed and the genome sequence of a *Digitaria* streak virus (DSV) from Vanuatu is included as an outgroup. Only viruses in the MSV-A group have been isolated from maize. All viruses in the other groups have been isolated from wheat, barley, or wild grass species.

The full genome nucleotide sequences of MSV-A isolates display relatively low degrees of diversity, with any two MSV-A isolates obtained from anywhere in Africa invariably having genome sequences that are more than 97% identical. MSV isolates from La Réunion share ~95% identity with mainland isolates.

Although Maize was first introduced at multiple points into Africa and its neighboring islands in the 16th century, it is apparent that the most recent common ancestor of all presently sampled MSV-A genomes only came into existence in the mid 1800s somewhere in South-Eastern Africa. It is also likely that this ancestral virus was the recombinant offspring of grass adapted-adapted parental viruses: one parent an MSV-B variant, and the other parent belonging to a presently unsampled MSV strain that is most closely related to MSV-F and MSV-G.

Transmission

In nature, MSV and other African streak viruses are neither seed nor contact transmissible and rely instead on transmission by cicadellid leafhoppers in the genus *Cicadulina* (including, among others, *C. mbila*, *C. storeyi*, *C. bipunctella zaeae*, *C. latens*, and *C. parazeae*). Of these, *C. mbila* is considered the most important MSV vector as it is the most widely distributed. Also, a greater proportion of *C. mbila* individuals are capable of transmitting the virus than is found in other *Cicadulina* populations. The virus may be acquired by leafhoppers at any developmental stage in less than 1 h of feeding with a minimum acquisition time of 15 s. A latent period within the vector, during which the virus cannot be transmitted, lasts between 12 and 30 h at 30°C. Once this latent period is over (signaled by the appearance of virus within the leafhopper's body fluids) the virus can be transmitted within 5 min of feeding. Once MSV has been acquired by a leafhopper, the insect will transmit the virus for the rest of its life.

Particle Structure

MSV particles (Fig. 4) consist of two incomplete icosohedra with a $T = 1$ surface lattice, comprising 22 pentameric capsomers each containing five coat protein (CP) molecules. Particle dimensions are 38 nm × 22 nm with 110 CP molecules in each virion packaging a ~2690 nt covalently closed mostly single-stranded circular DNA genome. The packaged DNA has annealed to it a complementary ~80 nt sequence believed to act as a primer for complementary strand synthesis following infection and uncoating.

Genome Organization

As with all other mastreviruses discovered to date, the MSV genome encodes four proteins: a movement protein (MP), a coat protein (CP), a replication-associated protein (Rep), and a regulatory protein (RepA). Whereas CP and MP are expressed off alternatively spliced virion sense transcripts, Rep and RepA are expressed off alternatively spliced complementary sense transcripts. MSV genomes also contain two intergenic regions: these are a short or small one (SIR), and a long or large one (LIR), which are the complementary sense strand and virion sense strand origins of replication, respectively (Fig. 5).

The Long Intergenic Region

Besides containing divergent RNA polymerase II-type promoters and other transcriptional regulatory features necessary for the expression of the complementary and virion sense genes, the LIR also contains sequence elements that are essential for replication. The

Fig. 4 Electron micrograph of MSV purified from infected maize, showing particles of 18 nm × 30 nm stained with uranyl acetate. Scale = 50 nm. Photograph courtesy of Kassie Kasdorf; copyright EP Rybicki.

Fig. 5 A schematic representation of the MSV LIR (a) and SIR (b), shown in context with the MSV genome. In (a) the main features of the MSV LIR are shown. These include a stem-loop structure with the loop's nonanucleotide sequence conserved among all geminiviruses and other rolling-circle systems. The site at which Rep introduces an endonucleolytic nick to initiate virion strand replication is shown. Iterated sequences (iterons) are shown in the V sense, with blue arrows indicating their location in the LIR. Iterons are potentially specific Rep-recognition sequences via which Rep may bind to the LIR. 5' of the stem-loop is a repeated GC-box, which binds host transcription factors. A series of T tracts 3' of the stem-loop may be involved in DNA bending of this region of the LIR. TATA boxes 5' and 3' of the stem-loop are potential C sense and V sense transcription initiation sites, respectively. In (b), the main features of the SIR include polyadenylation signals for V and C sense transcripts, and a primer-binding site on the plus strand. An ~80 bp DNA primer-like molecule, encapsidated with the viral genome and annealed to this site, is thought to be involved in initiating complementary strand replication. Both the MSV LIR and SIR are essential for viral replication.

most striking of these is an inverted repeat sequence that is capable of forming a stable hairpin loop structure. All geminiviruses sequenced to date have the highly conserved nonanucleotide sequence TAATATTAC within the loop sequence of similar hairpin structures: this sequence contains the virion sense strand origin of replication (*V-ori*;1).

A sequence 6–12 nt long occurring in all known mastreviruses between the TATA box that directs *rep/repA* transcription and the *repA* initiation codon is directly repeated in the stem near the *V-ori* hairpin, and is probably involved in *Rep* and/or *RepA* binding during replication.

The hairpin and two GC boxes on the 5' side of the stem also forms part of an upstream activator sequence (UAS) required for efficient CP expression. The GC boxes bind nuclear factors to the UAS and are known as the rightward promoter element (*rpe1*).

The Short Intergenic Region

The MSV SIR occurs between the termination codons of the *CP* and *rep* genes (Fig. 5) and contains the polyadenylation and termination signals of the virion and complementary sense transcripts. The SIR also contains the origin of complementary strand synthesis (*C-ori*). A small 80-nt-long primer-like molecule is bound to the SIR of encapsidated MSV DNA and, at the onset of an infection, probably enables synthesis of double-stranded DNA (dsDNA) replicative forms (RFs) of the genome from newly uncoated virion strand DNA.

The Complementary Sense Genes (*Rep* and *RepA*)

Rep is the only MSV gene product that is absolutely required for virus replication. In mastreviruses *Rep* is encoded within two open reading frames (ORFs) referred to as C1 and C2 (Fig. 5). Beginning at the same transcription initiation site, two C sense transcripts (1.5 and 1.2 kbp in size) are produced during MSV infections. Splicing of the larger transcript removes an intron, which permits expression of full-length *Rep* from the two ORFs.

It is very probable, although as yet unproven *in vivo*, that *RepA* is translated from both the unspliced 1.5 kbp transcript and the 1.2 kbp transcript. If expressed in infected cells, MSV *RepA* would have the same N-terminal 214-amino-acid sequence as *Rep*, but would have a different C-terminus. *RepA* is likely a multifunctional protein that modifies the nuclear environment to favor viral replication.

The N-terminal portions of *Rep* and *RepA* contain three conserved amino acid sequence motifs commonly found in replication-associated proteins of many extremely diverse rolling-circle replicons. Other significant landmarks include a plant retinoblastoma-related protein (pRBR) interaction motif (via which *RepA* binds to host pRBR molecules to manipulate the cell cycle), and oligomerization domains (via which *Rep* and *RepA* bind to other *Rep/RepA* molecules to form homo- and heterooligomers). It is also likely that the approximately 100 N-terminal amino acids of both *Rep* and *RepA* are involved in binding these proteins to the viral LIR during replication.

The C-terminal portion of *Rep* contains a dNTP-binding domain with motifs similar to those found in proteins with kinase and helicase activities. The dNTP-binding domain also sits within a region with similarity to the DNA-binding domains of the myb-related class of plant transcription factors: this domain may be functional in the induction of virus and/or host gene transcription.

The C-terminal portion of *RepA*, which is different from that of *Rep*, contains another potential transactivation domain also possibly involved in the regulation of virus and/or host gene expression. A second domain within the C-terminal portion of *RepA* possibly interacts with host proteins involved in developmental regulation.

The Virion Sense Genes (*MP* and *CP*)

Transcription of the MSV virion (V) sense genes is directed by two TATA boxes within the LIR 26 and 214 nucleotides 5' of the MP start codon. Each TATA box directs the production of different-sized transcripts, both of which terminate at the same place. Splicing of an intron within the MP portion of V sense transcripts appears to be an important determinant of relative MP and CP expression levels. Whereas CP is expressed from both long and short, spliced and unspliced V sense transcripts, MP is most likely only expressed from unspliced long transcripts.

The MP is post-translationally modified and contains a hydrophobic domain that may either facilitate its interaction with host cell membranes or be involved in homo- or hetero-oligomerization with the CP.

The N-terminal ~100 amino acids of the CP contain both nuclear localization signals and a sequence-nonspecific dsDNA- and ssDNA-binding domain. The CP and MP interact with one another and it is possible that this interaction is involved in trafficking of naked and/or packaged virus DNA from nuclei through nuclear pores, to the cell periphery, through plasmodesmata, and into the nuclei of neighboring cells.

Molecular Biology of MSV

Replication

As with other geminiviruses, MSV replicates by both a rolling-circle mechanism (rolling-circle replication, or RCR; (Fig. 6)) and a recombination-dependent mechanism (recombination dependent replication or RDR). As with other rolling-circle replicons, MSV

Fig. 6 Summary of the MSV infection process. Early during an infection following the synthesis of a dsDNA replicative form (RF; 1) RepA is most likely expressed and induces a cellular state in which viral DNA replication can occur (2). Rep is also expressed early and RCR begins (3). At a later point in the infection process, following genome amplification and possibly Rep and/or RepA induction of the V sense promoter, MP and CP are expressed (4), and movement and encapsidation occur (5). Represented here is movement of un-encapsidated ssDNA, but it should be noted that it is possible that dsDNA and/or encapsidated ssDNA may also be moved either cell to cell or systemically within the phloem of plants. Whereas the involvement of MSV CP and MP in movement has been demonstrated, the mechanics of the process are obscure. While the probable timing of events is indicated, it is unlikely, for example, that absolutely no MP and CP expression occurs during the earlier stages of the infection process. ssDNA is represented by blue lines, dsDNA by bold black lines, and RNA by orange lines.

replication is discontinuous with virion strand replication being initiated from the hairpin structure in the LIR and complementary strand synthesis being initiated from a short 80 nt primer-like molecule synthesized on the SIR of newly replicated virion strands.

Particle Assembly and Movement

Besides being the primary location of replication, the nucleus is also the site of virus particle assembly. CP molecules in the nucleus nonspecifically bind virion strands released during RCR (there is no known encapsidation signal in mastrevirus genomes), arresting the synthesis of new RF DNAs. Viral ssDNA molecules are packaged into particles that aggregate to form large paracrystalline nuclear inclusions. Crystalline arrays of MSV particles have also been detected outside nuclei within physiologically active phloem companion cells, and inside the vacuoles of dead and dying cells within chlorotic lesions. These lesions are caused by an as yet unexplained degeneration of chloroplasts in infected cells.

The mechanistic details of MSV cell-to-cell movement are still obscure, but it seems to involve an interaction between the CP, MP, and viral DNA. Besides requiring the coordinated interactions of viral gene products and DNA, the successful movement of MSV genomes from infected to uninfected cells is strongly dependent on the extent of plasmodesmatal connections between neighboring cells. Also, in maize it appears as though certain cell types are more sensitive to MSV infection than others. For example, in maize leaves the virus infects all photosynthetic cell types (e.g., mesophyll and bundle sheath cells) but despite abundant plasmodesmatal connections between photosynthetic, epidermal, and parenchyma cells, MSV is only rarely detectable in the latter two cell types.

It is unknown whether systemic movement of geminiviruses within plants simply relies on normal cell-to-cell movement to deliver genomic DNA into the phloem, or whether viral DNA is specifically packaged for long-distance transport. It is possible that

cell-to-cell movement might involve un-encapsidated ss- or dsDNA but that long-distance movement in the phloem might require encapsidation.

Long-distance movement of MSV within infected plants occurs via phloem elements and it is believed that MSV is incapable of invading the root apical, shoot apical, and reproductive meristems due to the absence of developed vasculatures in these tissues. Thus, the virus is not found in tissues that develop into gametes and is therefore not seed-borne. It also does not appear to travel within plants from sites of infection into older uninfected tissues.

Within the shoot apex where most productive MSV replication occurs, MSV first enters developing leaves at approximately plastochron five. While the virus is restricted to the developing leaf vasculature before plastochron 12, it is likely that the development of metaphloem elements at approximately plastochron 12 provides an opportunity for the virus to escape the vasculature into the photosynthetic cells of the leaf. Metaphloem develops with the abundant plasmodesmatal connections required for efficient loading of photoassimilates once the leaf emerges from the whorl. Before emergence, however, the developing photosynthetic tissues are still net importers of photoassimilates and the virus most likely moves into these cells through their plasmodesmatal connections with the metaphloem.

On the leaves, the pattern of chlorotic streak-like lesions that characterizes MSV infections is directly correlated with the pattern of virus accumulation within the leaves and the virus can only be acquired by leafhoppers from these lesions. The degree of chlorosis that occurs within lesions can differ between MSV isolates and is related to the severity of chloroplast malformation that occurs in infected photosynthetic cells.

Control of MSD

Although effective control of MSD in cultivated crops is possible with the use of carbamate insecticides, and it is possible to avoid leafhopper infestations by varying planting dates, the fact that small farmers cannot generally use these options means that the development and use of MSV-resistant crop genotypes is probably the best way to minimize the impact of MSD on African agriculture.

MSV resistance is associated with up to five separate alleles conferring a mixture of both dominant and recessive traits, none of which are sufficient by themselves to prevent MSV infections. Despite great successes achieved in the development of maize genotypes that tolerate MSV infection without significant yield loss, there has been only limited success in the field. For example, severe infections of so-called MSV-tolerant genotypes can occur when they are grown under environmental conditions different from those in which the plants were selected, meaning that distinct geographical growing areas may each require genotypes with MSV resistance that is tailored to those areas.

The problem facing breeders is that natural genetic resistance to MSD is not usually associated with desirable agronomic traits such as good yield. It can therefore be difficult to transfer resistance traits without also transferring undesirable characteristics. Moreover, the number of alleles involved means that successful breeding takes years for each release. Even in the absence of any predictive modeling of sporadic MSD outbreaks, most farmers would still prefer to gamble on the use of higher-yielding MSV-sensitive genotypes.

Efforts are also currently underway to introduce MSV resistance traits into commercial maize genotypes by genetic engineering. This could have the advantage of enabling the direct transfer of single-gene resistance, without linkage to undesirable characteristics, to many different breeding lines suited to different environmental conditions. However, up till now this strategy has been limited by negative public perception of genetically modified organisms, and the expensive and time-consuming risk assessment necessary to ensure a safe feed and food product.

MSD Epidemiology

There are loose correlations between MSD incidence and both environmental conditions and agricultural practices. Environmental influences on MSD epidemiology are mostly driven by a strong correlation between rainfall and leafhopper population densities. For example, drought conditions followed by irregular rains at the beginning of growing seasons tend to be associated with severe MSD outbreaks. Also, maize planted later in the growing season tends to get more severely infected than that planted at the beginning of the season, probably due to steady increases in leafhopper numbers and inoculum sources over the course of the season. As is the case with most insect-borne virus diseases, however, the incidence of MSD is erratic. Whereas MSD can devastate maize production in some years, in others it has only a negligible effect. The reason for this is that, apart from MSD epidemiology being strongly dependent on environmental variables, it is also the product of complex interactions between the various MSV leafhopper vector and host species, and an as yet unknown number of virus strains.

Leafhopper Vectors

Serious MSD outbreaks are absolutely governed by leafhopper acquisition and movement of severe MSV isolates from infected plants (wild grasses or crop plants) to sensitive, uninfected crop plants. The distance that MSV spreads from a source of inoculum

is determined by the movement behavior of leafhoppers. Distinct long- and short-distance flight morphs have been detected among certain *Cicadulina* populations. It is believed that the long-flight morphs are a migratory form and, as such, these may play an important part in the rapid long-distance spread of virulent MSV variants. Migratory movement is more common in certain *Cicadulina* species than in others and it is probably influenced by environmental conditions.

The dynamics of primary infection following leafhopper invasion of a susceptible maize crop are influenced by leafhopper population densities, the proportions of viruliferous individuals in populations, and virus titers within these individuals. Disease spread within individual maize fields is apparently linear when only a few viruliferous leafhoppers are involved in transmission, but becomes exponential once the number of insects exceeds one individual per three plants.

Plant Hosts

Although attempts to understand the dynamics of MSD epidemics have focused primarily on vector population dynamics and behavior, an important component of MSD epidemiology is the population density, turnover, and demographics of the over 80 grass species that are both MSV and vector hosts. Because *Cicadulina* species favor certain annual grass hosts for mating and oviposition, the species composition of grass populations that vary seasonally in any particular area will directly influence leafhopper population densities and feeding behaviors in that area.

The species composition and age distribution of grasses (including cultivated crops) in an area may also affect the amount of MSV inoculum available for transmission in that area. While MSV infects at least 80 of the 138 grass species that leafhoppers feed on, both the susceptibility of these grasses to MSV infection and the severity of symptoms that occur following their infection may be strongly influenced by a number of factors. While sensitivity to infection can vary substantially from species to species, it can also vary within a species with genotype and plant age at the time of inoculation: for example, plants from many species, including maize, generally become more resistant to MSV infection with age, thereby reducing the inoculum available for transmission to other plants.

The Virus

While efforts are underway to promote the widespread cultivation of MSV-resistant maize in Africa, surprisingly little is known about the MSV populations that will confront these new genotypes. Although to date eleven major MSV strain groupings have been discovered, it is unknown whether any other than the maize-adapted MSV-A strain play an important role in the epidemiology of MSD. MSV-B, -C, -D, and -E isolates only produce very mild symptoms in MSV-sensitive maize genotypes and are therefore unlikely to pose any significant direct threat to maize production. Mixed MSV-A and -B infections have, however, been detected in nature and there is also strong evidence of recombination occurring between these strains. It is therefore possible that MSV-B, and possibly other MSV strains, may indirectly influence MSD epidemiology through recombination with MSV-A-type viruses. Recombination has been linked with the emergence of a number of geminivirus diseases and it may also have contributed to the original emergence of MSV-A. It is plausible therefore that it could also eventually contribute to the evolution of MSV-A variants (or even variants of the other MSV strains) with elevated virulence in resistant maize genotypes.

Future Threat

MSV is rightly regarded as a significant potential threat to maize production outside of Africa: while the vectors do not occur outside of Africa, there is no obvious reason that they would not survive in other equatorial or temperate regions of the world such as the southern USA, South America and Eurasia. It is a distinct possibility that they could inadvertently spread, or even be deliberately taken, to these regions. If, following the establishment of a MSV vector species outside of Africa, MSV was then introduced, the virus would inevitably begin spreading within native grasses, cultivated maize and the other cereals that it is known to infect. As none of the maize varieties grown outside of Africa has the slightest resistance to MSV, the probability of severe economic consequences would be very high.

Glossary

Alphasatellite Alphasatellites are single-stranded DNA molecules of 1.0–1.3 kb, which behave like virus satellites in many respects. Unlike the true non-coding satellites, alphasatellites code for a protein that specifically catalyzes only their own replication initiation. They are encapsidated in particles formed by the capsid protein of the respective helper virus.

Clink The protein named Clink (for “cell cycle link”) interacts with the cell cycle regulator protein retinoblastoma and thereby modulates cell cycle regulation in favor of DNA synthesis (S-phase). Clink enhances nanovirus replication.

Enzyme-linked immunosorbent assay The enzyme-linked immunosorbent assay (ELISA) is a sensitive and versatile serological test with two common variants, the double antibody sandwich (DAS)-ELISA and the triple antibody sandwich (TAS)-ELISA. A double antibody sandwich (DAS)-ELISA consists of four steps (separated by individual washings): (1) the immunoglobulins (IgG) isolated from a virus-specific antiserum are used for coating of microtiter plates; (2) IgG-coated plates are incubated with extracts of samples to capture antigen, if present; (3) incubation with enzyme (usually alkaline phosphatase)-labeled IgG [see (1)]; (4) incubation with substrate of the respective enzyme followed by measuring its activity, for instance by colorimetry. The triple antibody sandwich (TAS)-ELISA differs from DAS-ELISA in step (3), which is

replaced by two steps consisting of (i) incubation with a specific (often monoclonal) antibody from a different animal species than the animal used to produce the coating IgG in step (1), and (ii) incubation with enzyme-labeled IgG raised against IgG of that same different animal species.

Replication initiator protein A replication initiator protein (Rep protein or Rep, also referred to as RC-Rep) initiates rolling-circle replication of DNA by cleaving double-stranded DNA at a defined sequence (replication origin). The Rep protein remains bound to the 5′ phosphate of the cleaved strand while a polymerase uses the liberated 3′ hydroxyl of the cleaved strand as primer for DNA synthesis. After one round of DNA synthesis another subunit of Rep cleaves the newly synthesized DNA at the replication origin sequence. The thus generated 3′ hydroxyl attacks the phosphotyrosyl ester bond of the bound Rep subunit, and by a nucleotidyltransfer a covalently closed circular single-stranded DNA molecule is created.

Rolling-circle replication Rolling-circle replication (RCR) is a process of unidirectional nucleic acid amplification, by which multiple copies of circular DNA or RNA molecules such as plasmids, bacteriophage- or eukaryote virus genomes are reproduced.

Satellites Satellites are subviral nucleic acids that depend for replication, systemic movement, encapsidation, and/or vector transmission on a helper virus, with which they co-infect a host; they do not code for a protein.

Introduction

In 1988 and 1991 a novel type of single-stranded DNA (ssDNA) virus causing yellowing and dwarfing diseases of legumes or banana was described. The viruses were persistently transmitted by aphids and not transmissible by sap. Unusually small, icosahedral particles measuring only 18–20 nm in diameter were isolated from infected plants. Because of the small size of the virions, the small size of individual genome components of only about 1 kb, and the dwarfing symptoms they caused, these

viruses were referred to as nanoviruses. They differ from geminiviruses, the other group of ssDNA plant viruses, in particle morphology, genome size, number and size of DNA components, genomic organization, mode of transcription, and vector species. Common with other ssDNA viruses including geminiviruses is the mode of nanovirus replication. Unlike bipartite geminiviruses, in which the two genomic DNAs are individually encapsidated, the nanovirus genome is multipartite and consists of six or eight ssDNAs each of which is individually encapsidated in a separate particle. Here we provide a brief synopsis of our current knowledge of these viruses.

Classification and Taxonomy

To date, eleven established and three recently identified members of the family *Nanoviridae* have been described. On the basis of differences in biology (host range, aphid vectors) and both genome size and organization, the family members (nanovirids) are subdivided into the genera *Nanovirus* and *Babuvirus*. The respective type species of these two genera are *Subterranean clover stunt virus* and *Banana bunchy top virus*. Three babuvirus and eight nanovirus species have been approved by the International Committee on Taxonomy of Viruses (ICTV). Information on the geographic distribution, important aphid vectors and some natural hosts of the nanovirids as well as the amount and type of genome sequence data available for them is given in Table 1.

Crops in mainly tropical and subtropical countries of the Old World harbor babuviruses, such as Abaca bunchy top virus (ABTV) in the Philippines, Cardamom bushy dwarf virus (CBDV) in India and Banana bunchy top virus (BBTV). The latter occurs widely on Pacific Islands (including Hawaii), in Australia and Indochina but has an erratic geographic distribution in South Asia and Africa. While Subterranean clover stunt virus (SCSV) occurs only on legumes in Australia, Milk vetch dwarf virus (MDV) has been reported

Table 1 Assigned and tentative members of the genera *Babuvirus* and *Nanovirus* of the family *Nanoviridae*

	Geographic distribution	Aphid vector	Natural host	Genome components	Complete sequences
Genus <i>Babuvirus</i>					
<i>Banana bunchy top virus</i> (type species)	Africa, Australia, Pacific Islands, southern Asia,	<i>Pentalonia nigronervosa</i>	<i>Musa</i> spp.	6	> 200
<i>Abaca bunchy top virus</i>	Borneo, Philippines	no data	<i>Musa</i> spp.	6	2
<i>Cardamom bushy dwarf virus</i>	India	<i>Micromyzus kalimpongensis</i>	<i>Elettaria cardamomum</i> , <i>Amomum subulatum</i>	6	> 160
Genus <i>Nanovirus</i>					
<i>Subterranean clover stunt virus</i> (type species)	Australia	<i>Aphis craccivora</i> , <i>Aphis gossypii</i> , <i>Acyrtosiphon pisum</i>	<i>Trifolium subterraneum</i> and other legumes	8	2
<i>Black medic leaf roll virus</i>	Austria, Sweden, Azerbaijan	<i>Aphis craccivora</i> , <i>Acyrtosiphon pisum</i>	<i>Medicago lupulina</i> , <i>Pisum sativum</i>	8	3
<i>Faba bean necrotic yellows virus</i>	Near East, North Africa, Ethiopia, Spain	<i>Aphis craccivora</i> , <i>Aphis fabae</i> , <i>Acyrtosiphon pisum</i>	<i>Vicia faba</i> and other legumes	8	8
<i>Faba bean necrotic stunt virus</i>	Ethiopia, Morocco, Azerbaijan, Iran	<i>Aphis craccivora</i> , <i>Acyrtosiphon pisum</i>	<i>Vicia faba</i> , <i>Lens culinaris</i> , <i>Phaseolus vulgaris</i> and other legumes	8	8
<i>Faba bean yellow leaf virus</i>	Ethiopia	No data	<i>Vicia faba</i>	8	1
<i>Milk vetch dwarf virus</i>	China, Japan, Bangladesh	<i>Aphis craccivora</i> , <i>Acyrtosiphon pisum</i> , <i>Megoura viciae</i> , <i>Myzus persicae</i>	<i>Vicia faba</i> and many legumes and non-legumes i.e., <i>Nicotiana tabacum</i> , <i>Carica papaya</i> , <i>Catharanthus roseus</i>	8	8
<i>Pea necrotic yellow dwarf virus</i>	Germany, Austria, Hungary, Denmark, Serbia, Netherlands	<i>Aphis craccivora</i> , <i>Aphis fabae</i> , <i>Acyrtosiphon pisum</i> , <i>Megoura viciae</i>	<i>Pisum sativum</i> , <i>Vicia faba</i> and other legumes	8	8
<i>Pea yellow stunt virus</i>	Austria	No data	<i>Pisum sativum</i>	8	1
<i>Cow vetch latent virus</i> ^a	France	No data	<i>Vicia cracca</i>	8	1
<i>Parsley severe stunt-associated virus</i> ^a	Germany	No data	<i>Petroselinum crispum</i>	7 ^b	1
<i>Sophora yellow stunt-associated virus</i> ^a	Iran	No data	<i>Sophora alopecuroides</i> et al.	8 ^c	2

^aRecently described viruses not yet assigned to the genus *Nanovirus* by ICTV.

^bNo DNA-U4 found; four different types of DNA-R found but M-Rep not experimentally identified.

^cTwo different DNA-C types found; four different DNA-R types found but M-Rep not experimentally identified.

from several legumes and non-legumes in Japan, China, and recently also in Bangladesh, suggesting that it has a wide distribution in several other countries of South-east Asia. Whereas Faba bean yellow leaf virus (FBYLV) was reported only from Ethiopia, Faba bean necrotic yellows virus (FBNYV) appears to have a much wider geographic distribution in West Asia, the Middle East, North- and East Africa and Europe (Spain). Faba bean necrotic stunt virus (FBNSV) has been found in Ethiopia, Morocco, Azerbaijan and Iran. Also from Iran, Sophora yellow stunt associated virus (SYSaV), a nanovirus infecting *Sophora alopecuroides*, a leguminous fodder crop, was reported. During recent years a number of nanoviruses have been described from Central- and Northern Europe. This situation is exemplified by Pea necrotic yellow dwarf virus (PNYDV) from Germany, Denmark, the Netherlands, Austria, Hungary and Serbia, Black medic leaf roll virus (BMLV) from Austria, Sweden and Azerbaijan, Pea yellow stunt virus (PYSV) from Austria, and Cow vetch latent virus (CvLV) from France. The most recently identified nanovirid is Parsley severe stunt associated virus (PSSaV) from Germany, the only nanovirus potentially restricted to a non-leguminous host. No nanovirids have as yet been found in the Americas. All available evidence suggests that nanovirids are quite variable in their biological and molecular properties.

Particle Properties

Virions of the nanovirids are not enveloped, 17–20 nm in diameter, and presumably of an icosahedral $T = 1$ symmetry structure containing 60 subunits. Capsomeres may be evident, producing an angular or hexagonal outline (Fig. 1). Virions are stable in Cs_2SO_4 but may not be stable in CsCl . The buoyant density of virions is about 1.24–1.30 g/cm^3 in Cs_2SO_4 , and 1.34 g/cm^3 in CsCl . They sediment as a single particle component in sucrose rate-zonal and isopycnic Cs_2SO_4 density gradients.

Virions have a single capsid protein (CP) of about 19 kDa. No other proteins have been found associated with virions. Each ssDNA component is encapsidated in a separate particle. Virions are strong immunogens. Most nanovirid species are serologically distinct from one another.

Genome Organization

Based on DNA sequence analyses of a range of geographical isolates there is evidence that six and eight DNAs form the genome of a babu- and nanovirus, respectively (Table 1). Both encapsidated genomic nanovirid DNAs and nanovirid-associated DNAs (*Alphasatellitidae*) are covalently closed ssDNA circles of about 1 kb in size. A characteristic feature of all nanovirid and nanovirid-associated DNAs are two short (8–13 nt) inverted repeat sequences flanking a stretch of 11–13 nt containing a conserved nonanucleotide motif: TATTATTAC in babuviruses and TAGTATTAC in nanoviruses (exception: PSSaV, which has TATTATTAC). These sequences have the potential to form a stem-loop structure in ssDNA or a cruciform extrusion in dsDNA. Comparable DNA-sequence or DNA-structure motifs, also referred to as stem-loop or hairpin-loop, are common in all ssDNA viruses that multiply their genome by rolling-circle replication (see below). Sequences 5' and 3' of the inverted repeats are also conserved among the individual genome components, and their respective extensions in both directions are quite variable depending on the virus. This region has been designated common region stem-loop (CR-SL). In extreme cases sequences of up to 160 nt (PSSaV) or 250 nt (MDV), located 3' of the inverted repeat are conserved among individual genomic DNAs.

Fig. 2 Genome organization of nanovirids and associated alphasatellites. Individual genomic DNAs are represented as circles. A knob, often also referred to as hairpin, indicates the position of the inverted repeat sequences flanking the conserved nonanucleotide at the origin of viral strand replication. Component designations are displayed inside each circle. Arrows represent coding sequences of the respective encoded proteins. Protein names are given below DNA component names. Constituents of the babuvirus genome are framed in red and those of the nanovirus genome in green. DNAs of the top row have homologs in viruses of both genera; DNAs of the bottom row are unique for either nano- or babuviruses as indicated by the respective frame. Alphasatellites differing in numbers and types are frequently found associated with members of each genus of the *Nanoviridae*, hence included in the black frame. Graphics courtesy of I. Grigoras.

Apart from the CR-SL both babu- and nanoviruses possess a second conserved region that is common to all genomic DNAs. In babuviruses it is located 5' of the inverted repeats at distances that vary from about 50 nt to about 350 nt. The region is referred to as common region major (CR-M) and has a length of around 60 nt in ABTV, 65–92 nt in BBTV and 75–80 nt in CBDV. There is no such rather uniform CR-M in nanoviruses. Instead, short stretches of conserved sequences from 17 to 34 nt constitute a so-called common region II (CR-II), which is located about 70 nt 5' of the CR-SL. In some cases (e.g., FBVLV) there is no CR-II, and in others (e.g., MDV and PNYDV) rather long sequence stretches 5' of the inverted repeats are conserved between all genomic DNAs, except DNA-R. The genomic DNAs of nanoviruses are about 100 nt shorter than those of babuviruses and the coding region of DNA-R terminates closely 5' of the CR-SL. This restricts the possibility for longer common conserved sequences due to constraints dictated by aa conservation. Hence only short CR-II sequences are common to all genomic nanovirus DNAs whereas longer CR-II stretches may occur between nanovirus genomic DNAs other than DNA-R.

The genomic information of each nanovirid is distributed over six or eight different molecules of the aforementioned ssDNA type (Table 1). Upon infection, the circular ssDNAs are converted into circular double-stranded DNAs (mini-chromosomes) that serve as templates for gene expression. Each of these DNA molecules contains a single open reading frame of positive (virion-sense) polarity, preceded by a promoter sequence with a TATA box and followed by a polyadenylation signal (Fig. 2).

The fact that a typical set of respectively six or eight distinct DNAs has been consistently identified from babu- and nanoviruses suggests that the babuvirus genome consists of six DNAs and the nanovirus genome of eight DNAs. DNA-R, -S, -C, -M and -N have been identified from all nanovirids (Fig. 2, Table 1). DNA-U1, -U2 and -U4 homologs are typical for all nanoviruses but are absent from babuvirus genomes. In contrast, DNA-U3 is restricted to babuviruses and is absent from nanovirus genomes.

Transcript analyses of BBTV demonstrated a single virion-sense transcript per genome component. A minor transcript was found internal of the DNA-R ORF. For nanoviruses only transcripts of FBNYV and SCSV DNA-R and FBNYV DNA-C, along with a FBNYV-associated alphasatellite (see below) transcript have been mapped in detail. They are 3'-polyadenylated and their 5' ends map shortly after the TATA sequences preceding the respective ORFs. Consistent with these transcript analyses is the notion that each nanovirid DNA encodes a single gene defined by the respective ORFs and their flanking transcription initiation and termination signals. Interestingly the DNA-R transcripts of the two nanoviruses studied, FBNYV and SCSV, are terminally redundant by 54–161 nt (FBNYV) and 49 nt (SCSV). Considering the positions of TATAA box- and polyadenylation sequences of DNA-R molecules of all nanoviruses, such a terminal redundancy is predicted to be a unique and distinctive feature of nanovirus DNA-R components in general. Its biological significance remains, however, unknown.

Although eight DNAs (DNA-R, -S, -C, -M, -N, -U1, -U2, and -U4) had invariably been found associated with nanovirus infections, the question of 'how many DNAs constitute a nanovirus genome' had remained open for some time until experimental infection using individually cloned FBNSV DNAs became possible. In this way, the type of disease symptoms induced as well as the efficiency of vector transmission of the thus reconstituted virus could be analyzed. Due to this considerable technical accomplishment it was demonstrated that without DNA-R, DNA-S and DNA-M no infection was possible. DNA-C, DNA-U1, and DNA-U2 were required for

efficient disease development and vector transmission but not absolutely essential. Interestingly, infections devoid of DNA-N resulted in a disease phenotype indistinguishable from infections with wild-type virus. However, neither cowpea- nor pea aphids, the most efficient nanovirus vectors, were able to transmit virions produced in DNA-N-less infections. Hence DNA-N encodes the transmission helper factor postulated earlier. Finally, DNA-U4 proved to be non-essential for infection and sustained virus transmission under experimental conditions. Although these results were obtained with FBNSV in faba bean, it is very likely that they are equally valid for other nanoviruses. Experimental infection using cloned genome DNAs has been successfully demonstrated also for BMLRV, FBNYV and PNYDV. To date, no comparable experimental infection with DNAs of any babuvirus has been achieved.

There are indications that the genome organization of nanoviruses can sometimes be even more complex. In infections by each of the recently discovered SYSAV and PSSaV four DNA-R-like components were identified. However, which one of them encodes a Rep protein capable of acting as a master-Rep protein, i.e., catalyzing replication initiation of the other genomic DNAs, has not been determined. These findings illustrate well that the current picture of nanovirus genome organization may still be in flux.

Properties and Functions of Nanovirid Proteins

In addition to the capsid protein (CP) of about 19 kDa encoded by DNA-S, at least 5–7 non-structural proteins are encoded by the other 5 or 7 genomic DNAs of nanovirids (Table 1, Fig. 2). Besides acting as the structural protein required for virion formation, the protein encoded by DNA-S of BBTV has also been identified as a silencing suppressor.

One of the best-studied nanovirid proteins is the ca. 33 kDa replication initiator protein (Rep) encoded by their DNA-R. It belongs to the vast protein family of rolling-circle replication (RCR) initiator proteins of ssDNA viruses, bacteriophages, RCR plasmids and RCR-transposable elements (helitrons). Nanovirids express a unique Rep protein that is essential for replication initiation of all genome segments, six in case of babuviruses and eight in case of nanoviruses. This Rep protein recognizes specific sequence motifs in the so-called origin region, DNA stretches flanking the inverted repeat sequences that are shared by all genome components. By contrast to the Rep proteins encoded by DNA-R, those encoded by the nanovirid-associated alphasatellites are not able to trigger replication initiation of any nanovirid genome component. This led to the name ‘master replication initiator protein’ (M-Rep) for the DNA-R-encoded protein.

Several salient features characteristic of RCR-initiator proteins have been demonstrated also for a nanovirus (FBNYV) M-Rep protein, e.g., origin DNA cleavage and nucleotidyltransferase activity and ATPase activity. Also, the three-dimensional structure of the DNA-binding and endonuclease domain of FBNYV M-Rep has been determined, revealing a striking similarity to those of geminiviruses, circoviruses, parvoviruses, polyomaviruses and papillomaviruses. By analogy to geminivirus Rep proteins, nanovirus M-Rep proteins are probably also the smallest helicases of the superfamily 3 helicases (S3H), experimental proof however pending. Replication initiator and capsid proteins are, in addition to the so-called ‘stem-loop’ motif in the ssDNA, common elements shared by the very large group of so-called CRESS (circular Rep-encoding single-stranded DNA) viruses.

The third protein essential for nanovirid infection, apart from CP and M-Rep, is the 13–14 kDa protein encoded by DNA-M. Experimental evidence obtained for the protein encoded by DNA-M of BBTV indicates that it is involved in cell-to-cell movement. A stretch of 25–30 hydrophobic residues at its N-terminus is conserved in all its nanovirid homologs, consistent with a function as movement protein (MP). As shown for the BBTV CP, the MP of BBTV is also able to act as a suppressor of RNA silencing by reversing systemically established gene silencing.

The protein encoded by DNA-C is 19–20 kDa in size and has an N-terminal F-box sequence and the aa motif LxCxE characteristic for proteins binding to the cell-cycle regulator protein retinoblastoma (pRB). Moreover, the DNA-C encoded protein has been shown to interact with pRB. Therefore, the name “Clink” for ‘cell cycle link’ protein was coined for it.

Based upon evidence obtained for the activity of the BBTV DNA-N encoded 17–18 kDa protein it was proposed to act as a nuclear shuttle protein (NSP). In addition to that it has been shown that the NSP homologs of FBNSV and PNYDV are mandatory for virus transmission by vector aphids. Another biological property of a nanovirus NSP is its interaction with cellular proteins involved in stress granule formation, as shown for PNYDV. It is speculated that this way NSP may inhibit stress granule formation, a protective cellular response to virus infection.

Little is known about the biochemical properties or biological functions of the proteins encoded by DNA-U1, -U2, -U3, and -U4, where “U” stands for “unknown function”. As mentioned above, FBNSV DNA-U1 and DNA-U2 influence disease symptoms and the total amount of virions produced. It is plausible to assume that this is due to the action of the respective encoded proteins U1 (17–18 kDa) and U2 (14–15 kDa). The experimental disruption of a nuclear localization signal in the U1 protein altered its subcellular localization, yet no specific function was thus revealed for the U1 protein.

The U3 protein deduced from an ORF on DNA-U3 of BBTV is ca. 9 kDa in size. There are no data about its potential function. A transcript spanning the BBTV DNA-U3 ORF has been mapped. A homologous ORF is absent in the DNAs termed U3 of ABTV and CBDV. It remains, therefore, questionable whether these DNAs can be considered being true homologs of BBTV DNA-U3.

The deduced U4 protein encoded by DNA-U4 of the nanoviruses has a size of ca. 13 kDa. The fact that DNA-U4 homologs were detected in all nanovirus infections except those by PSSaV underpins the importance of the respective DNA-U4 product in natural infections. This notion appears valid despite the observation that DNA-U4 was not required for development of disease symptoms in experimental infections of faba bean seedlings with FBNSV. Moreover, FBNSV lacking DNA-U4 was serially transmitted to faba bean by aphids for >2 years. To date, only in planta protein-protein interaction data of bi-molecular fluorescence complementation assays employing PNYDV U4 protein are available and revealed auto-interaction and interaction with the PNYDV movement protein (MP).

Nanovirid Replication

The knowledge about geminivirus replication can largely be transposed also to nanovirid replication. Upon inoculation by aphid vectors virions enter host cells, presumably phloem parenchyma cells. As shown for BBTV and geminiviruses the ssDNAs are converted with the help of virion-encapsidated primers into double-stranded transcriptionally active mini-chromosomes. Most probably, this step occurs in the nucleus, but whether virions or only ssDNAs enter the nucleus is not known. Once a sufficient amount of M-Rep protein is available, a subunit of M-Rep cleaves the phosphodiester backbone of the origin DNA between nt T7 and A8 of the nonanucleotide TAG/TTATT-AC, becomes covalently linked to the 5' phosphate of A8 via its active site tyrosine (Y79 in case of FBNYV M-Rep), and a host DNA polymerase utilizes the 3'-OH of T7 as primer for DNA synthesis. After one round of replication, a second subunit of M-Rep cleaves the newly synthesized nonanucleotide sequence between T7 and A8, becomes linked to the 5' phosphate of the newly synthesized A, and the 3'-OH of T7 attacks the phosphotyrosyl ester bond between the first M-Rep subunit and the DNA, which leads to a nucleotidyltransfer of the M-Rep-linked 5' phosphate to the newly available 3'-OH. As a result, a phosphodiester bond is formed resulting in a liberated circular single-stranded DNA molecule, and a free tyrosine of the first M-Rep subunit, a step that requires no energy. These steps are repeated as long as rolling-circle replication continues. This so-called 'nicking and joining' activity by M-Rep proteins of DNA with the conserved nonanucleotide sequence has been experimentally demonstrated in vitro for BBTV and FBNYV as well as for one Rep of a FBNYV-associated alphasatellite. Replication of nanovirus DNAs is enhanced by the action of Clink, the nanovirid-encoded cell cycle modulator protein that is assumed to re-program the cell cycle of non-proliferating plant cells towards S-phase.

One interesting and quite unique characteristic of nanovirus replication has been discovered using FBNSV as a model: multiplication of each individual genomic DNA to a different and component-specific maximum level, the so-called genome formula. This genome formula differs between the two hosts faba bean (*V. faba*) and barrel medic (*Medicago truncatula*) and is also different in its vector, the pea aphid *A. pisum*.

Taxonomy and Phylogeny

Nanovirids share a set of five homologous DNA components, referred to as DNA-R, -S, -C, -M and -N (Fig. 2). Three other DNAs (DNA-U1, -U2 and -U4) encoding proteins of as yet unknown functions have been identified from nanoviruses and one further DNA (DNA-U3) only from babuviruses. Viruses of the individual species typically have narrow host ranges. Under natural and experimental conditions all nanoviruses only infect dicotyledonous plants. Most nanoviruses have largely overlapping host ranges and predominantly infect a range of leguminous species (*Fabaceae*) and a few other dicotyledonous species (Table 1), whereas babuviruses have been reported only from a few monocotyledonous species, such as the *Musaceae* or *Zingiberaceae*. Since these plants are colonized by a restricted number of (often monophagous) aphid species, the nanoviruses studied for their biological properties are transmitted by the cowpea aphid *Aphis craccivora*, the pea aphid *Acyrtosiphon pisum* and some other aphid species predominantly feeding on legumes. The vector of PSSaV, a nanovirus identified from parsley, a non-leguminous host, is unknown. The currently known babuviruses are vectored by the banana aphid *Pentalonia nigronervosa* and *Micromyzus kalimpongensis*.

The other major differences between babu- and nanoviruses are that (1) nanovirus DNA components range in size from 962 to 1045 nt and are thus slightly smaller (by ca. 100 nt) than those of babuviruses (1013–1116 nt), (2) babuviruses are serologically unrelated to members of the genus *Nanovirus*, and (3) nanoviruses share low levels of aa sequence identities ranging from 14% to 58% in individual genes with babuviruses. Moreover, nanovirus DNA-R transcripts are terminally redundant unlike those of the babuviruses.

Phylogenetic analyses of the nt sequences of nano- and babuviruses demonstrated (Fig. 3) that the five babuvirus sequences representing three species form a cluster clearly distinct from the nanoviruses. The latter consist of a group of eight related species from Asia, Europe and North Africa and three more distantly related species each from Australia (SCSV), Iran (SYSaV) and Europe (PSSaV).

Comparison of the deduced aa sequences of the five proteins encoded by DNA-R, -S, -C, -M, and -N by representative isolates of the nanovirid species listed in Table 1 shows that the master Rep protein (M-Rep) is the most conserved protein. It has an overall aa identity of 80%–97% between members of the same genus and 54%–58% between the two genera. The second most conserved protein is the NSP with 55%–91% intra-genus aa identity and 41%–50% inter-genus aa identity. Capsid protein, MP and Clink protein follow with maximum intra-genus aa identities of 88%, 81% and 76%, respectively. The sequence conservation of these proteins between babu- and nanoviruses is lower than that of M-Rep and NSP with maximum sequence identities of 33% (MP), 27% (CP) and 25% (Clink), respectively.

If one considers intra-genus variability of the respective proteins there is no significant difference in variability among homologous nanovirus proteins and among homologous babuvirus proteins. The variability of nanovirus proteins appears slightly higher, but this is probably due to the greater number of nanovirus genomes sequenced, including one from parsley, a non-leguminous species. With respect to the currently used criteria for species discrimination in the family, the reader is referred to the latest ICTV description of the family *Nanoviridae*.

Based on similarities in particle morphology and size and based on the identification of an alphasatellite-like DNA (1.3 kb), Coconut foliar decay virus (CFDV), the causal agent of a severe disease of coconut palms in Vanuatu, is listed as an unassigned species of the family *Nanoviridae*. However, following rolling-circle amplification and deep sequencing analyses of historic and fresh samples twelve distinct circular DNAs have recently been identified. Sequence analysis suggested that nine of the DNAs represent alphasatellites (Fig. 4) and that the CFDV genome is possibly tripartite, consisting of an alphasatellite-like DNA (1.3 kb), a 1.3 kb DNA encoding a capsid protein related to that of grabloviruses (*Geminiviridae*), and a unique DNA-gamma (641 nt) that

Fig. 3 Maximum likelihood phylogenetic tree of nanovirid genomes. Individual DNAs of homologous genome components were concatenated in the order DNA-R, -S, -C, -M, -N and aligned using Muscle. The tree was constructed in MEGA7 using the GTR + G + I nt substitution model and is mid-point rooted. The scale bar corresponds to 0.1 substitutions per site. Percent bootstrap support of 5000 non-parametric replicates is shown. Branches below 50% support are collapsed.

may encode a movement protein. Thus, CFDV differs clearly from established members of the family *Nanoviridae* not only in genomic organization, DNA sequence as well as in the type of insect vector (planthopper versus aphids), implicating that CFDV possibly represents a member of a new family of plant viruses.

Nanovirid Evolution

Virus genomes that consist of single-stranded nucleic acids are known to undergo rapid sequence evolution. This is also true for nanovirids as has been shown for FBNSV. It has a rate of 1.8×10^{-3} substitutions per nt per year, the highest substitution rate among ssDNA viruses and is only outrivalled by those of influenza A viruses and human immunodeficiency viruses. Any potential disadvantage caused by such an elevated nt substitution rate is probably compensated for by the fact that every type of genome component acts individually as a quasi-species-like swarm of molecules.

Also, reassortment of individual genomic DNAs or groups thereof and recombination between them would alleviate the genetic load imposed by such a high nt substitution rate. Indeed, both recombination and reassortment of genome component has been observed in nanovirids, for instance BBTv and a range of nanoviruses. In fact, given the extent of common sequences shared by several genomic DNAs of the hitherto identified nanoviruses, recombination between them is probably frequent during replication.

Interestingly, each type of nanovirus genomic DNA does not need to be present simultaneously in an individual cell of a host plant to trigger a productive infection, as has been shown recently for FBNSV. This finding led to the assumption that nanovirus infection, exemplified by FBNSV, does not necessarily need to operate at the level of individual cells but rather at the level of an organism, here a plant host. Such a behavior, coined “multicellular way of life”, is unique for multipartite viruses and represents a novel concept in virology. A multicellular way of life would alleviate the problems caused by the very high multiplicity of infection required for a virus with an octopartite genome if it were productively operating only at the level of a single cell. This observation also fits with the proposition that the de novo origin of multipartite ssDNA viruses may postdate the emergence of multicellular eukaryotes.

Nanovirid-Associated Alphasatellites

In addition to the genomic DNAs of nanovirids, a large number of additional DNAs encoding Rep proteins have been found associated with almost all nanovirid infections. These Rep-encoding DNAs are quite diverse and phylogenetically distinct from any nanovirid DNA-R, however related to Rep-encoding DNAs associated with begomoviruses and CFDV (Fig. 4). Collectively, these DNAs are now referred to as alphasatellites (*Alphasatellitidae*). Using conventional approaches of sequence analysis, nanovirus-associated alphasatellites were often detected prior to the essential nanovirid DNA-R components. This is explained by the fact that these alphasatellites are much more abundant than any genomic DNA of the nanovirus they associate with, as was revealed by

Fig. 4 Maximum likelihood phylogenetic tree of nanovirid DNA-R components and nanovirid-associated alphasatellites. DNAs were aligned using Muscle and a mid-point rooted tree was constructed in MEGA7 using the GTR + G + I nt substitution model. The scale bar corresponds to 0.1 substitutions per site. Percent bootstrap support of 1000 non-parametric replicates is shown. Branches below 80% support are collapsed.

deep sequencing analyses. Deep sequencing also permitted the detection of up to seven or fourteen distinct alphasatellites in single plants infected with PSSaV or SYSaV, respectively. Begomovirus- and CFDV-associated alphasatellites are larger (ca. 1300 nt) than nanovirid-associated alphasatellites (ca. 1000 nt) due to the inclusion of an A-rich sequence within their non-coding region. Nanovirus-associated alphasatellites are individually encapsidated in nanovirid-like particles. Proof of their encapsidation stems from the first sequenced FBNYV-associated Rep-encoding DNA and was recently also provided by sequencing DNA extracted from CFDV virions. In contrast to the activity of the M-Rep proteins encoded by DNA-R, alphasatellite-encoded Rep proteins are only capable of initiating replication of their cognate DNA, as shown for FBNYV- and BBTV-associated alphasatellites. Despite the fact that almost all nanovirid infections are accompanied by varying numbers of alphasatellites, little is known about their influence on the pathogenicity or epidemiology of the respective helper viruses. In this context it is noteworthy that two begomovirus-associated alphasatellites were shown to act as silencing suppressors.

Recently alphasatellites were classified in the newly established family *Alphasatellitidae*, subdivided in the subfamilies *Geminialphasatellitinae* (five genera) and *Nanoalphasatellitinae* (seven genera).

Transmission and Host Range

Tissue Tropism and Means of Transmission

SCSV and FBNYV have been shown to replicate in inoculated protoplasts. All assigned viruses are restricted to the phloem tissue of their host plants and are not transmitted mechanically and through seeds. Apart from graft transmission, vector transmission had been the only means of experimentally infecting plants with nanovirids for a long time, until infectivity of purified FBNYV virions by biolistic bombardment was demonstrated. Meanwhile, vector transmission of virus derived from experimental infections of various hosts by cloned nanovirus genome components is possible for BMLRV, FBNSV, FBNYV, and PNYDV, and has been used to identify the virus-encoded helper factor of aphid transmission.

Transmission by Aphids

Under natural conditions, all nanovirids are transmitted by certain aphid species, in which they can persist for many days or weeks without replicating in their vectors. At least 10 aphid species belonging to the tribes *Macrosiphini* and *Aphidini* were reported as vectors of nanovirids. Whereas only one aphid species, the banana aphid (*Pentalonia nigronervosa*) and *Micromyzus kalimpongensis* has been reported as respective vector of BBTV and CBDV, several aphid species transmit FBNYV, MDV, and SCSV. The cowpea aphid (*Aphis craccivora*) appears to be the major natural vector of these viruses as it is the most abundant aphid species on legume crops in the afflicted areas and was among the most efficient vectors under experimental conditions. Other aphid vectors of FBNYV are the black bean aphid (*Aphis fabae*) and the pea aphid (*Acyrtosiphon pisum*). SCSV has been reported to be vectored also by the cotton aphid (*Aphis gossypii*), the green peach aphid (*Myzus persicae*) and the potato aphid (*Macrosiphum euphorbiae*), and PNYDV by the cowpea- and pea aphid and the vetch aphid (*Megoura viciae*). The vector aphids of ABTV, FBVLV, PYSV, SYSaV, and PSSaV have not been determined (Table 1).

Transmission studies showed that aphids are able to transmit BBTV, FBNYV and SCSV following short acquisition and inoculation access feeding periods of about 30 min each. Although viruliferous aphids often retain transmission ability for life, nanovirids do not multiply in their insect vectors. Together with the observation that longer acquisition and inoculation access feeding periods resulted in higher transmission rates, the long persistence of nanovirids in their insect vectors indicates that they are transmitted in a circulative persistent manner similar to that of luteoviruses. In contrast to observations for luteoviruses, however, immunofluorescence localization of BBTV in the banana aphid *Pentalonia nigronervosa* indicates that BBTV antigens occur in cells of the anterior midgut and the principal salivary glands. This translocation resembles that of the geminiviruses, the other family of plant ssDNA viruses.

For FBNYV it has been demonstrated that purified virions alone are not transmissible by its aphid vector, regardless of whether they are acquired from artificial diets using membrane feeding techniques or directly microinjected into the aphid's hemocoel. However, faba bean seedlings biolistically inoculated with intact virions or viral DNA developed symptoms typical of FBNYV infections and were efficient sources for FBNYV transmission by aphids. These observations together with results from complementation experiments suggest that FBNYV (and other nanovirids) require a virus-encoded helper factor for its vector transmission that is absent from purified virion preparations. Using the individually cloned DNAs of FBNSV and PNYDV, it has recently been demonstrated that the proteins encoded by DNA-N of FBNSV and PNYDV are mandatory for virus transmission by vector aphids. This sets the nanovirids clearly apart from other viruses transmitted in a circulative manner, such as geminiviruses and luteoviruses. The uniqueness of nanovirids is also substantiated by the observation that the so-called genome formula of FBNSV in its vector, the pea aphid *A. pisum*, differs from those in two host plants, faba bean (*V. faba*) and barrel-medick (*Medicago truncatula*).

Host Range

Nanoviruses often have largely overlapping host ranges by infecting over 50 legume species and only a few non-legume species under experimental and natural conditions. FBNYV, MDV and SCSV naturally infect a range of leguminous species, whereas BBTV and ABTV have been reported only from *Musa* species and closely related species within the *Musaceae*, such as abaca (*M. textilis* Née) and ensete (*Ensete ventricosum* Cheesem). There are no confirmed non-*Musa* hosts of BBTV. Symptoms of BBTV include plant stunting, foliar yellowing, and most characteristic dark green streaks on the pseudostem, petioles, and leaves. CBDV has been reported from black cardamom (*Amomum subulatum*) and green cardamom (*Elettaria cardamomum*), two closely related species of the family *Zingiberaceae*. All economically important natural hosts of FBNYV, MDV, and SCSV are legumes, in which these viruses generally cause plant stunting and a range of foliar symptoms, such as leaf deformations and chlorosis or reddening. Although FBNYV infects >50 legume species and only few non-legume species (*Stellaria media*, *Amaranthus* and *Malva* spp.) under experimental and natural conditions, major legume crops naturally infected by FBNYV are faba bean, lentil (*Lens culinaris*), chickpea (*Cicer arietinum*), pea (*Pisum sativum*), French bean (*Phaseolus vulgaris*) and cowpea (*Vigna unguiculata*). Likewise, SCSV experimentally infects numerous legume species, but its economically important natural hosts only include subterranean clover, common bean, faba bean, pea, and medics. In addition to *Sophora alopecuroides*, SYSaV was found in Iran in a few other legumes, such as milk vetch (*Astragalus* sp.), chickpea, licorice (*Glycyrrhiza glabra*), and lentil but also in a non-leguminous plant, wild rue (*Peganum harmala*; *Nitrariaceae*). MDV is known to cause yellowing and dwarfing in Chinese milk vetch (*Astragalus sinicus* L.), a common green manure crop in Japan, as well as in cowpea, faba bean, pea, and soybean. The host range of MDV appears to be larger than that of most other nanoviruses as a number of non-leguminous plants have been reported as experimental hosts of MDV, and natural infections by MDV have recently been recorded from tobacco (*Nicotiana tabacum*; *Solanaceae*) in China and papaya (*Carica papaya*; *Caricaceae*) and periwinkle (*Catharanthus roseus*; *Apocynaceae*) in Bangladesh. This and the recent identification of a novel type of nanovirus from parsley (*Petroselinum crispum*; *Apiaceae*) in Germany may indicate that there are further nanovirids which naturally infect several other non-leguminous plants.

Epidemiology and Control

Based on symptomatology and transmission characteristics, luteoviruses were earlier suspected as the causative agents of several diseases now known to have a nanovirid etiology. Unlike luteoviruses, however, nanovirids generally cause more severe

symptoms. In many nanovirid-host combinations, early infections lead to very severe effects and even premature plant death. The disease caused by BBTV is considered the most serious viral disease of banana worldwide. SCSV and FBNYV are also of considerable economic importance as they have caused serious diseases of subterranean clover in Australia and of faba bean in Egypt, respectively, leading to repeated crop failures. The same applies to PNYDV, which has occurred in certain years (e.g., 2016) at an epidemic scale in central European countries where it caused considerable yield losses in legume crops such as green pea and faba bean. Since PNYDV seems to have a wide geographic distribution in Central Europe, it poses a potential threat to legume production in Europe. This threat might be increased by future changes in climatic conditions that favor survival of aphid vector populations during milder winters in Central Europe and thus facilitate the spread of PNYDV. The economic importance and control of other nanovirids such as ABTV, FBYLTV, PYSV, SYSAV and CvLV cannot be commented on as they were identified from single samples and the biological properties of these viruses have not been studied so far.

Disease control is based on the results from ecological and epidemiological studies. Since nanoviruses and legume luteoviruses are transmitted by almost the same aphid species, are phloem-limited in their host plants, cause nearly identical symptoms and are not seed-transmitted, they appear to have similar ecologies. Because of this similarity and because luteoviruses have been better studied than nanoviruses, information generated in relation to the control of luteoviruses are useful in the development of control strategies for nanoviruses. Control measures can be subdivided into three major categories: (1) those aimed directly at the virus, (2) those aimed directly at the vector, and (3) integrated approaches, which combine all possible components in a way to complement each other and be applied as one control package.

Since virus control is a complex topic, only two examples of virus control, one for a babuvirus (CBDV) in a perennial crop and the other for a nanovirus (FBNYV) in an annual crop are briefly presented. The control of BBTV is dealt with in a separate article (see BBTV (*Nanoviridae*)).

CBDV causes foorkey disease of large cardamom by inducing a remarkable reduction in size of leaves of the infected plants, stimulating proliferation of a large number of stunted shoots arising from the rhizome, transforming the inflorescence into leafy vegetative parts and suppressing fruit formation. CBDV-infected plants remain unproductive and gradually degenerate. The primary spread of disease from one area to another is through infected rhizomes and further spread within the plantation is by aphids. For the management of foorkey disease a regular rogueing of diseased plants by uprooting and immediately destroying them is recommended. As preventive measures, cardamom growers should use CBDV-free planting material preferably seedlings, avoid suckers as planting material from diseased areas and avoid keeping nurseries in the vicinity of infected plantations.

In countries of West Asia and North Africa, FBNYV can occur at a high incidence and cause severe yield losses in cool-season legumes, such as chickpea, faba bean, lentil and pea. A significant decrease in disease incidence can be expected if sources of infection are eliminated from within or near crops. In practice, this is not easy and it is rather impossible to eliminate all weed hosts of FBNYV. Prior to advocating such an approach for FBNYV control, more information on the relative importance of wild legumes and weeds as sources of FBNYV infection is needed. Severe epidemics of FBNYV can be prevented by proper timing of sowing dates, avoiding peak aphid population and by spraying the fields with appropriate insecticides once or twice during the period when viruliferous aphids introduce FBNYV to the crop. Another measure to prevent further spread and to decrease disease incidence is to eliminate or reduce primary infection foci as sources of infection from within fields. Since sources of resistance to FBNYV have been identified in wild legume species a classical breeding approach might be used for incorporating resistance into established cultivars of some of the aforementioned cool-season legumes.

Diagnosis

Nanovirids can be detected and identified by a range of methods, such as electron microscopy (EM), serology, polymerase chain reaction (PCR), isothermal rolling-circle amplification (RCA) and various sequencing techniques. Because of the small size of the nanovirid particles, which can be easily confused with cell constituents, EM (i.e., use of leaf extracts for adsorption preparates) is not the method of choice for nanovirid detection. The virions can only be visualized following particle purification and by immunosorbent EM using nanovirid-specific antisera for coating of EM grids.

Most nanovirid species are serologically distinct from one another. BBTV and the two other babuviruses are serologically unrelated to members of the genus *Nanovirus*. However, antisera and some monoclonal antibodies (MAbs) to BBTV cross-react strongly with ABTV and CBDV. Therefore, BBTV antibodies have been used for the detection of ABTV and CBDV, the two other babuviruses. Of the 10 MAbs raised to BBTV, only two reacted with ABTV. This is consistent with a CP aa sequence difference of about 20% between ABTV and BBTV. On the contrary, antisera to FBNYV and SCSV cross-reacted weakly with SCSV and FBNYV, respectively, in Western blots and immunoelectron microscopy but not at all in double-antibody sandwich enzyme-linked immunosorbent assays (DAS-ELISA), indicating that the serological relationship between these two nanoviruses is remote. However, MDV antigen reacts strongly not only with an antiserum to FBNYV in DAS-ELISA but also with the majority of MAbs to FBNYV in TAS-ELISA, indicating a close serological relationship between FBNYV and MDV (CP aa sequence identity of about 83%). Some of the FBNYV MAbs also allowed detection and differentiation of PNYDV, PYSV, and BMLRV, indicating that these nanoviruses share certain epitopes with FBNYV. However, species-specific MAbs are indispensable for specific detection of all nanovirids by serological means.

Under routine conditions and for the analysis of large numbers of samples, nanovirids are typically tested in TAS-ELISA using a cross-reactive antiserum (or a mixture of antisera) for coating of plates and a mixture of broad-spectrum MAbs for antigen detection.

Samples that give positive reactions can then be used for aphid transmission experiments, PCR analysis and various sequencing techniques. After the initial screening of samples using TAS-ELISA, PCR or immuno-capture PCR using nanovirus component-specific primers have been used for the molecular characterization of nanovirids. Also, isothermal multiple displacement amplification (MDA) or RCA using Phi29 polymerase has become a widely used technique to enrich nanovirus DNAs in DNA preparations from tissue samples or even ancient particle preparations. For instance, the multiple DNAs associated with coconut foliar decay disease were uncovered this way from virion samples stored for about 30 years.

At present, RCA- or PCR-amplified DNA is routinely used for deep sequencing analyses and has yielded considerable insights into the diversity of known nanovirids and has also led to the discovery of PSSaV, a novel and quite different nanovirus.

Concluding Remarks

Apart from graft transmission and biolistic bombardment with purified virions, vector transmission had been the only means of experimentally infecting plants with nanovirids for a long time, until infectivity of cloned nanovirus DNA was demonstrated for FBNSV and fully infectious and aphid transmissible virus could be reconstituted this way. Due to this technical achievement functional analyses of individual nanovirus genes have become possible. Meanwhile infection using cloned genome DNAs has been successfully demonstrated also for BMLRV, FBNYV and PNYDV and allowed the application of reverse genetics to studying also nanoviruses, which was not possible before. As a consequence, the experimental independence of vector transmission has substantially advanced nanovirus research during the last years and yielded new and unexpected findings about nanovirus biology. In particular, the recent discovery of a ‘multicellular lifestyle’ of these multipartite ssDNA plant viruses represents a remarkable feat that would have been impossible without reverse genetics.

satRNA Satellite RNA

TED Translational enhancer domain

UTR Untranslated region

Glossary

Procedovirinae A subfamily in the family *Tombusviridae*, which RNA-dependent RNA polymerase is translated after the read through of a stop codon (from the Latin “*procedo*”, go ahead).

Read-through Read-through consists of the “translation” of a stop codon, such that the synthesis of a larger protein is

allowed. It is a common phenomenon in viruses, and it has a regulatory function.

Riboviria A higher taxonomic rank including all viruses possessing a RNA genome.

Tombusviridae A family of single-stranded positive sense RNA viruses within realm *Riboviria*.

Taxonomy and Classification

As the representative of a monotypic group, *Tobacco necrosis virus A* (TNV-A) was among the 16 groups of plant viruses described in 1971, and became the type species of the genus *Necrovirus* when it was established in 1995. Since 2012, the genus *Necrovirus* does not exist anymore as such, but phylogenetic analyses of the RNA-dependent RNA polymerase (RdRp) and movement proteins 1 and 2 (MP1 and MP2) supported the division of the former genus *Necrovirus* into two genera, *Alphanecrovirus* and *Betanecrovirus*. Due to the expression of their RNA-dependent RNA polymerase after translational readthrough of a stop codon, both genera belong to the subfamily *Procedovirinae* in the family *Tombusviridae* (realm *Riboviria*).

The genus *Alphanecrovirus* comprises four definitive member species, i.e., the type species *Tobacco necrosis virus A* (TNV-A), *Olive latent virus 1* (OLV-1), *Olive mild mosaic virus* (OMMV), and *Potato necrosis virus* (PoNV). The genus *Betanecrovirus*, besides the type species *Tobacco necrosis virus D* (TNV-D), includes two additional virus species: *Beet black scorch virus* (BBSV), and *Leek white stripe virus* (LWSV). *Chenopodium necrosis virus* (ChNV), formerly a member of the genus *Necrovirus* and for which sequence data are not available, is now an unassigned species in the subfamily *Procedovirinae*.

Virion Properties, Structure and Composition

Virus particles are very stable, resist temperatures in excess of 90°C, and chloroform, ether and non-ionic detergents. TNV-A virions sediment as a single component with a coefficient ($S_{20,w}$) of 118S and have buoyant density of 1.399 g ml⁻¹ at equilibrium in CsCl.

Icosahedral virions are approximately 28 nm in diameter, have angular profile and a capsid made up of 60 copies of a trimer consisting of three chemically identical but independent protein subunits (A, B, and C) stabilized by Ca²⁺ ions, arranged in a $T = 3$ lattice. Subunit size ranges from 24 to 27 kDa (BBSV and LWSV, respectively) to 29–30 kDa (other viral species). The capsid has a smooth appearance as protein subunits have an internal R domain and a shell (S), but lack the protruding domain proper of members of the majority of the other genera in the family *Tombusviridae* (Fig. 1).

Necro-like virions encapsidate one molecule of single-stranded, positive-sense RNA, neither capped at the 5' end, nor polyadenylated at the 3'-terminus, approximately 3.6–3.7 kb in size, constituting c. 19% of the particle weight.

Genome Organization and Expression

The monopartite genome contains four open reading frames (ORFs) which, in the order from the 5' to the 3' terminus, code for replication-associated proteins (ORF1 and ORF1-RT), movement proteins (ORF2 and ORF3), and the coat protein (CP) (ORF4). Some species possess a fifth ORF either located in the 3' terminal region (TNV-A) or in the middle of the genome (TNV-D^H and
